Anteroposterior renal pelvic diameter is perhaps the most commonly used technique for diagnosing congenital hydronephrosis. Both Arger et al.[4] and Grignon et al.[5] considered an anteroposterior diameter ≥10 mm to be predictive of abnormal outcome. In addition, Arger et al.[4] suggested follow-up scans in any fetus with an anteroposterior diameter of ≥5 mm. Data from the current investigation indicate that a threshold of 10 mm is too high. For example, 68% of fetuses with postnatally confirmed congenital hydronephrosis would be missed before 24 weeks' gestation (Table III). In contrast, a threshold of 4 mm yields a sensitivity of 100%. While the false-positive rate is higher with a 4 mm threshold, the goal is to identify all "at risk" fetuses. In addition, the false-positive rate declines as gestational age advances, falling to only 24% near term. After 33 weeks' gestation, a threshold of 7 mm can be used while still maintaining 100% sensitivity.

The second analyzed ultrasonographic parameter was the ratio of the anteroposterior diameters of the renal pelvis and kidney. Both Arger et al.[4] and Kleiner et al.[6] suggested that a ratio exceeding 0.50 should be used for prenatal diagnosis of congenital hydronephrosis. Before 24 weeks' gestation, this threshold would fail to detect 60% of postnatally confirmed lesions; after 24 weeks, nearly 50% of affected fetuses would remain undetected (Table IV). To achieve a sensitivity of 90% to 100%, an anteroposterior pelvis/kid-

Table VIII. Anteroposterior pelvic diameter: Thresholds for counseling

CH, Congenital hydronephrosis confirmed postnatally; *S/C*, postnatal surgery and/or evidence of renal compromise.

ney ratio of 0.28 is recommended. While this ratio is associated with a high false-positive rate in early pregnancy, progressive decline in the rate of false-positive results is noted as gestation advances.

The third examined biometric approach to prenatal diagnosis of congenital hydronephrosis was the ratio of the transverse diameters of the renal pelvis versus the kidney. Jeanty and Romero[7] described this technique in 1984 and considered a ratio ≥0.5 to be abnormal. In our study population this threshold identified only 52% of confirmed lesions before 24 weeks' gestation and missed 23% to 40% of affected fetuses during later pregnancy (Table V). A transverse pelvis/kidney ratio of 0.30 appeared more ideal, identifying nearly 100% of cases at all gestational ages. As with previously cited techniques, the false-positive rate declines with advancing gestational age.

The kidney circumference/abdominal circumference ratio was originally described by Grannum et al.[8] Although this method was developed as a means of quantifying renal enlargement in cystic kidney disease, an increased ratio also might be anticipated in congenital hydronephrosis. On examination of our data, a kidney circumference/abdominal circumference ratio of 0.28 appeared optimal during the midtrimester although sensitivity decreased to only 59% during late pregnancy (Table VI).

Of all analyzed techniques for prenatal diagnosis of congenital hydronephrosis, the anteroposterior diameter of the renal pelvis is simplest and has sensitivity and false-positive rates that are equal or superior to those of other ultrasonographic approaches. Follow-up studies are warranted in 3 to 4 weeks if an anteroposterior pelvic diameter is ≥4 mm before 33 weeks or ≥7 mm after 33 weeks. Postnatal follow-up studies are recommended if persistent renal pelvic dilatation is evident. Neonatal ultrasonographic evaluation should be postponed for several days after delivery to assure that the infant is well hydrated and the full extent of any potential obstruction appreciated. If abnormal, additional diagnostic studies including intravenous pyelography and renal scintigraphy may be helpful in further defining the lesion, as well as in delineating appropriate medical management.

Table VIII provides useful information for counseling parents when a diagnosis of congenital hydronephrosis is suspected. For example, before 24 weeks' gestation, there is a 41% chance of postnatally confirmed congenital hydronephrosis if the anteroposterior pelvic diameter is between 4 and 6 mm and a 19% risk for impaired renal function and/or surgery. The risk for adverse outcome increases to 40% if the anteroposterior diameter is between 7 and 9 mm and approaches 73% if ≥10 mm.

It is clear from this study that congenital hydronephrosis is a clinically significant birth defect. Overall, 69% (31/45) of affected infants had related morbidity as defined by abnormal renal function and/or the need for surgical intervention. We hope this investigation clarifies appropriate ultrasonographic criteria for diagnosis of congenital hydronephrosis and provides useful guidelines for counseling and management of this common congenital malformation.

Endomyocardial ultrastructural findings in preeclampsia

**John R. Barton, MD,[a] Adam K. Hiett, MD,[a] William N. O'Connor, MD,[b]
Steven E. Nissen, MD,[c] and John W. Greene, Jr., MD[a]**
Lexington, Kentucky

Ultrastructural findings in endomyocardial biopsy specimens obtained during cardiac catheterization in a patient with severe preeclampsia are described. Intramyocardial vessels revealed prominent swelling of the endothelial cell cytoplasm. In addition, cardiac myocyte mitochondria showed swelling and clearing within the matrix. Endomyocardial ultrastructural injury occurs in severe preeclampsia. (AM J OBSTET GYNECOL 1991;165:389-91.)

Key words: Preeclampsia; ultrastructure; injury, vascular

Although the exact cause of preeclampsia remains unknown, there are specific ultrastructural aspects that are consistently detected when tissues from patients with preeclampsia are studied. Presented are ultrastructural findings of the left ventricular endomyocardium from a patient with severe preeclampsia.

Case report

A 31-year-old white woman, gravida 4, para 1, aborta 2, presented at 35 weeks 5 days' gestation with a 4-day history of worsening shortness of breath. Pulmonary edema was diagnosed and intravenous furosemide and supplemental oxygen were initiated without improvement. Nasotracheal intubation was performed and mechanical ventilation was begun. A femoral arterial line was inserted for blood pressure and arterial blood gas monitoring. A nitroprusside drip was initiated at a dose

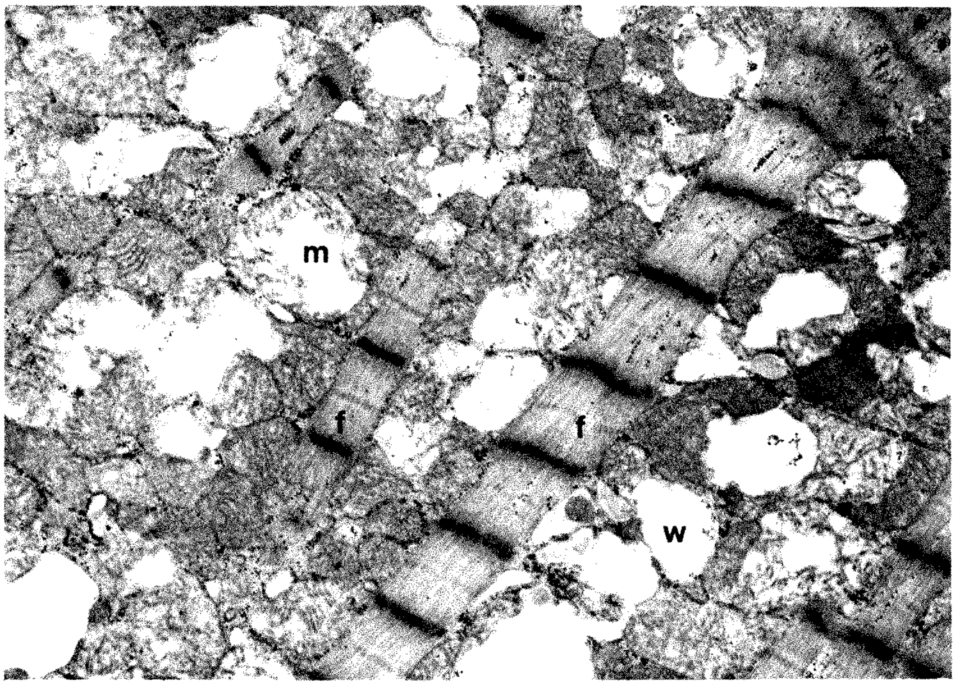

Fig. 2. Electron micrograph of cardiac myocyte cytoplasm showing extensive acute change in mitochondria, primarily including swelling and clearing of matrix *(m)* and laminated roll or whorls *(w)*. Myocardial fiber *(f)*. Glutaraldehyde fixation and Epon embedment. (Uranyl acetate–lead citrate. Original magnification × 17,000, reduced 24%.)

of 0.25 μg/kg/min to reduce afterload. Systolic blood pressure rapidly fell to 50 mm Hg. Blood pressure failed to recover despite discontinuation of the nitroprusside and utilization of dopamine and dobutamine infusions. The peripheral pulses were diminished. An intraaortic balloon counterpulsation device (9.5 F, Data Scope Corp., Paramus, N.J.) was inserted through the femoral artery. Initial setting was 1 : 1.

Invasive hemodynamic monitoring findings were consistent with pulmonary edema. An echocardiogram revealed normal chamber dimension; however, there was impaired global systolic function with an ejection fraction of 35%. Intravenous furosemide was continued, resulting in a brisk diuresis. Within 12 hours of admission, the clinical "picture" was more consistent with severe preeclampsia, with a mean arterial blood pressure of 127 mm Hg, proteinuria (3 +) and a serum uric acid level of 9.4 mg/dl. Intravenous magnesium sulfate was administered and a repeat cesarean section was performed. A 2640 gm infant was delivered with Apgar scores of 8 and 9 at 1 and 5 minutes, respectively.

On postoperative day 1, the patient underwent extubation. Mean arterial pressure decreased to 93 mm Hg. Cardiac output ranged from 4.7 to 6.2 L/min. Afterload reduction was accomplished with hydralazine and captopril. Intraaortic balloon counterpulsation was also discontinued on the first postoperative day.

On postoperative day 7, because of the atypical presentation and to evaluate for peripartum cardiomyopathy, the patient underwent a cardiac catheterization and left ventricular endomyocardial biopsies. Findings included left ventricular dysfunction with anterolateral hypokinesis, but with preserved left ventricular systolic and diastolic function. No valvular disease was identified, and minimal coronary artery disease was present. Microscopic examination of the endomyocardial biopsy specimen revealed myocardial fiber hypertrophy with focal interstitial fibrosis. There was neither myocarditis nor evidence of endocardial fibrosis, amyloidosis, or granulomas. Electron micrographs of the myocardium revealed a diffuse and extensive degenerative process. Small blood vessels revealed prominent swelling of endothelial cell cytoplasm with luminal narrowing, bleb formation, and trapping of red blood cells (Fig. 1). In addition, cardiac myocyte mitochondria showed swelling and clearing within the matrix, while the intramyocardial cristae retracted against the lateral membrane (Fig. 2).

Comment

Microvascular abnormalities in the heart of this patient were similar to changes seen in other organ systems of women with preeclampsia. Ultrastructural changes in the placental bed of patients with preeclampsia include swollen and eroded endothelium with reduction of the lumen.[1] Electron microscopy of endomyocardial biopsy specimens from our patient showed a similar swelling of endothelial cells with capillary luminal narrowing. The ultrastructural changes of endothelial injury from preeclampsia are postulated to be the result of both diffuse cytoplasmic and organellar swelling.[1] This swelling may then lead to erosion of the endothelium with progression to whole-cell desquamation.

The ultrastructural changes in mitochondria were similar to those recently described by Shanklin and Sibai.[2] Mitochondria were diffusely enlarged with clearing within the matrix and frequently displayed cristae bent against the lateral membrane. In the more advanced forms of disruption, a laminated roll or whorl was noted.

This case report demonstrates that the previously described ultrastructural changes in the endothelium of the placental bed, uterine boundary vessels, and renal glomeruli from patients with preeclampsia also may be noted in the microvasculature of the heart on endomyocardial biopsy. In addition, recently described changes in myometrial smooth muscle cell mitochondrial ultrastructure observed in patients with preeclampsia also were noted in heart muscle cells. Further study is indicated to determine whether comparable vascular injury occurs in other body sites during preeclampsia, as well as to investigate the organelle changes responsible for these findings.

We thank Douglas R. Shanklin, MD, for the review of the electron micrographs.

High risk of human papillomavirus infection and cervical squamous intraepithelial lesions among women with symptomatic human immunodeficiency virus infection

**Sten H. Vermund, MD, PhD,[a,b] Karen F. Kelley, MPH,[a] Robert S. Klein, MD,[a,c]
Anat R. Feingold, MD, MPH,[a] Klaus Schreiber, MD,[d] Gary Munk, PhD,[e] and
Robert D. Burk, MD[b,f,g]**
Bronx, New York

We investigated the relationship of human papillomavirus (by cervicovaginal lavage and Southern blot), human immunodeficiency virus, and squamous intraepithelial lesions in 96 high-risk women in the Bronx, New York. Antibodies for human immunodeficiency virus were detected in 51 (53%) women. Of the 33 women with symptomatic human immunodeficiency virus infection, 23 (70%) had human papillomavirus infection compared with 4 of 18 (22%) asymptomatic women who were human immunodeficiency virus seropositive and 10 of 45 (22%) uninfected women ($p < 0.0001$). The rate of squamous intraepithelial lesions was 52% (14 of 27) for women with both viruses detected, 18% (6 of 34) for women with either virus detected, and 9% (3 of 35) for uninfected women. Among symptomatic human immunodeficiency virus–infected women, a strong association between human papillomavirus infection and squamous intraepithelial lesions was demonstrated (odds ratio, 12; 95% confidence interval, 1.3 to 108). Risk was highest for younger women from ethnic or racial minority groups. Advanced human immunodeficiency virus–related disease, with its associated immunosuppression, seems to exacerbate human papillomavirus–mediated cervical cytologic abnormalities. Public health measures are needed to provide Papanicolaou smear screening and appropriate clinical follow-up and treatment for women at high risk for human immunodeficiency virus infection. (AM J OBSTET GYNECOL 1991;165:392-400.)

Key words: Human immunodeficiency virus, human papillomavirus, cervix, sexually transmitted diseases, squamous intraepithelial lesions

Immunosuppression, whether from chemotherapy, malignancy, or infection, has been shown to be associated with higher than expected rates and advanced pathologic consequences of human papillomavirus (HPV) infection.[1-4] Immunosuppressed women from a wide range of age, racial, and socioeconomic groups have been reported to manifest greater HPV frequency and pathogenicity.[3,4] Therefore the cervix is likely to be a target organ for HPV-related pathologic conditions among women who have been immunosuppressed by a variety of causes. Studies in pregnant women, renal allograft recipients, Hodgkin's disease patients, and other women on a regimen of immunosuppressive drugs have suggested a dose-response relationship between severity of HPV-induced lesions and increased immunosuppression.[5,6] In addition, immunosuppressed women often respond poorly to conventional treatment for HPV-induced cytologic lesions, and residual infection often leads to the progression of a cytologic lesion even after treatment.[1,2]

Women with human immunodeficiency virus (HIV) infection have been reported to show a high prevalence of cervical intraepithelial neoplasia or squamous intraepithelial lesions, although most published or presented studies to date have not included a comparable uninfected control group.[6] A few controlled studies have suggested an association of HIV with cervical cytologic abnormality.[7-13] Cytologic evidence from these studies suggests that HIV infection may promote the pathologic consequences of HPV, which is analogous to the course of HPV infection among other immunosuppressed patients.[7,8] HIV may affect local cervical immunity by diminishing quantity or function of Langerhans' cells, a plausible mechanism for pathophysiologic changes.[6,14,15] Preliminary reports using

molecular diagnosis of HPV in some studies suggest that advanced HIV-related clinical disease or immunosuppression seems to predispose to higher rates of cervical intraepithelial neoplasia,[6, 13, 16-18] including a preliminary report of a subset of the women reported here.[19] However, other preliminary studies found no such association.[20, 21] The strong relationship that exists between HPV, HIV, and anal dysplasia among homosexual men who engage in unprotected receptive anal intercourse[22, 23] suggests a common HIV immunosuppression–mediated mechanism of HPV-related neoplastic changes in selected genital epithelial tissues in both women and men.

This study was designed to investigate the hypothesis that HIV-infected women who are also infected with HPV, detected by molecular hybridization, are more likely to have cervical cytologic abnormalities than are women with only one or neither virus. Important potential confounding factors are considered. Additionally, we have sought to determine whether stage of HIV infection, i.e., asymptomatic or symptomatic, may be associated with frequency and severity of cervical cytologic abnormalities.

Methods

Subjects. The subjects included 97 women with known HIV serologic status, 96 of whom had cervicovaginal lavage samples that were sufficient for HPV determination and were thus included in this analysis. The protocol was approved by the hospital institutional review board for the protection of human subjects. Seventy-three were women with a history of heroin use attending a Bronx, New York, methadone maintenance program affiliated with a major medical center and enrolled in a longitudinal study of the natural history of HIV infection.[19] Twenty-two participants were recruited from women who were enrolled in a study of HIV transmission among heterosexual partners of intravenous drug users at the same medical center.[7] One woman was a transfusion recipient of HIV-seropositive blood, who was included because she was from the same geographic and socioeconomic background as the other subjects. HIV antibody status was determined by enzyme immunoassay (ELISA, DuPont) and confirmed by Western blot; positive results by both methods were noted in 51 (53%) of the 96 subjects.

Consecutive subjects were enrolled on the basis of availability of study personnel and provision of informed consent at the time of their visits. Women in the methadone program who were coming for annual physical examination and women who were enrolled in a heterosexual transmission study were recruited at the time of a research visit. A few high-risk women were recruited from the infectious disease clinic or medical ward of the hospital at a time when a Papanicolaou smear was medically indicated. All sexually active women with known or obtainable HIV serologic results from these recruitment environments were deemed eligible for the study.

After written informed consent was obtained, a brief questionnaire was administered to obtain demographic characteristics and smoking and gynecologic history. A pelvic examination was performed and a Papanicolaou smear was obtained with a cotton swab and a wooden Ayres spatula. Endocervical samples were then collected for *Chlamydia trachomatis*, *Neisseria gonorrhoeae*, and herpes simplex virus cultures with a calcium alginate swab on an aluminum shaft for chlamydia and a cotton swab for gonorrhea and herpes simplex virus. Exfoliated cervicovaginal cells were obtained for HPV determination by cervicovaginal lavage as previously described.[19, 24-26]

Patient health status (e.g., rashes, chancres) and syphilis serologic results by Venereal Disease Research Laboratory test or reagin precipitin reaction were assessed at or near the time of the pelvic examination. If a positive test was noted, a fluorescent treponemal antibody test was performed. Syphilis was diagnosed if primary or secondary lesions were present with positive results for all tests or if the Venereal Disease Research Laboratory test or reagin precipitin reaction titer had not fallen after prior treatment for clinically confirmed syphilis.

Cytology. Papanicolaou smears were interpreted and classified, by personnel who were blinded to patient HIV and HPV status, on the basis of the Bethesda Terminology and Classification system for cervical and vaginal cytology.[27] All abnormal and most normal smears were confirmed by one of the authors (K.S.). For analyses, we compared subjects with smears considered benign (negative or showing only reactive or reparative changes) with those having "positive" smears (smears providing evidence of squamous intraepithelial lesions or cancer). To provide a more striking clinical comparison, most analyses were repeated to exclude subjects from the analysis whose Papanicolaou smears showed only reactive or reparative changes; these repeat analyses contrasted characteristics of women with completely negative smears with those of women with squamous intraepithelial lesions. Women were referred for colposcopic examination where clinically indicated; however, follow-up is incomplete and results of additional gynecologic evaluations are therefore not presented.

Molecular biology. Deoxyribonucleic acid (DNA) extracted from cervicovaginal cells was tested for human papillomavirus DNA by *Pst* I restriction analysis and Southern blot hybridization, with a mixed probe of HPV DNA types 11, 16, and 18. Hybridizations were performed under conditions of low stringency (i.e.,

tm = −40° C), followed by a low-stringent wash, after which filters were exposed for 1 to 3 days. Then a subsequent wash at high stringency was followed by exposure for 1 to 2 weeks.[24] All HPV DNA determinations were made without the knowledge of any laboratory or clinical findings.

Clinical assessment. Chart review of all medical records of the 51 HIV-infected women was performed to assess signs and symptoms of HIV disease, and classification was made according to the Centers for Disease Control scheme.[28] On the basis of data from the clinical and research records, women were classified into one of four groups: group 1, acute infection; group 2, asymptomatic infection; group 3, persistent generalized lymphadenopathy; and group 4, other diseases associated with HIV infection. No patient had evidence of acute infection, and patients in groups 3 and 4 were combined into one category for purposes of analysis, comparing HIV-infected persons without signs or symptoms (termed *asymptomatic*) with HIV-infected persons with signs or symptoms (termed *symptomatic*).

Seven subjects (all symptomatic HIV infected) were being treated with zidovudine and three others were taking acyclovir as prophylaxis for recurrent HSV infection. Eight subjects were participating in a double-blind, placebo-controlled trial of zidovudine efficacy in asymptomatic, HIV-seropositive persons. These 18 HIV-infected women had behavioral and sociodemographic characteristics similar to those of the other 33 HIV-positive patients and were analyzed with their appropriate clinical symptom group.

Biostatistics. Standard statistical methods were used for data analysis including χ^2 tests (with Yates' correction for 2 × 2 tables) or two-tailed Fisher's exact tests when sample size did not permit use of the χ^2. Odds ratios and Mantel-Haenszel odds ratios with 95% confidence intervals were used to measure strength of stratum-specific and overall associations in multivariate analyses. One-way analysis of variance was used to compare average age of subgroups.

Evidence of squamous intraepithelial lesions at cervical cytologic testing was the outcome studied. Women

were grouped into six categories on the basis of the two major independent variables: (1) symptomatic HIV-infected and HPV-infected, (2) symptomatic HIV-infected and HPV-uninfected, (3) asymptomatic HIV-infected and HPV-infected, (4) asymptomatic HIV-infected and HPV-uninfected, (5) HIV-uninfected and HPV-infected, and (6) HIV-uninfected and HPV-uninfected. For some analyses, categories 1 and 3 (HIV-infected and HPV-infected), 2 and 4 (HIV-infected and HPV-uninfected), and 5 and 6 (HIV-uninfected) were collapsed. One summary analysis combined categories 3 through 6 into one group (asymptomatic HIV-infected or HIV-uninfected). Given the heterogeneous rates for HIV, HPV, and squamous intraepithelial lesions in various racial and ethnic categories (see Results), the key analyses that associate HIV and HPV and that associate HIV, HPV, and Papanicolaou smear results were stratified by race. Age was controlled with stratum-specific analyses comparing women <34 years old (median, See results) with women ≥34 years old.

Results

Pregnancy status, sexual behavior, and sociodemographic characteristics including age and education were similar between groups of subjects (Table I). Nonwhite subjects were disproportionately represented among HIV-infected women, as has been reported previously.[29]

HIV and HPV status. The clinical status of HIV infection among the 51 HIV-seropositive women included 18 asymptomatic subjects and 33 symptomatic subjects with persistent generalized lymphadenopathy, oral candidiasis, or acquired immunodeficiency syndrome. Thirty-seven (39%) of the study participants had cervicovaginal lavage specimens that were positive for HPV infection. Among the 51 HIV-infected women, 27 (53%) of the cervicovaginal samples contained HPV DNA, whereas 10 (22%) of 45 HIV-seronegative women were infected with HPV ($p < 0.005$). This association was attributed in full to the excess in HPV infection among symptomatic women (70%); the frequency of HPV infection in asymptomatic HIV-infected women (22%) was identical to that among HIV-uninfected women (Table II).

Cervical cytology. Seventeen of 51 (33%) HIV-seropositive women had Papanicolaou smear abnormalities demonstrating squamous intraepithelial lesions, compared with six of 45 (13%) HIV-seronegative women ($p < 0.05$). Of HPV-infected women, 17 (46%) of 37 had squamous intraepithelial lesions, whereas 6 (10%) of 59 HPV-uninfected women had squamous intraepithelial lesions ($p < 0.0005$).

Among symptomatic HIV-infected women, a significant association between HPV infection and cervical lesions showing squamous intraepithelial lesions was noted (odds ratio, 12; 95% confidence interval, 1.3 to 108; Table III). With smaller numbers of patients and fewer adverse outcomes, the associations of HPV infection and squamous intraepithelial lesions for asymptomatic HIV-infected and HIV-uninfected women showed a positive trend but did not reach statistical significance (Table III). The overall association of HPV and positive Papanicolaou smear was significant, controlling for HIV infection and clinical status (Mantel-Haenszel odds ratio, 5.8; 95% confidence interval, 1.5 to 18).

The rate of cervical abnormality was 57% (13 of 23) for women infected with both HIV and HPV and symptomatic for their HIV infection, 18% (7 of 38) for women infected with either virus alone or infected with both viruses but asymptomatic for HIV infection, and 8.6% (3 of 35) for women not infected with either virus. In a comparison of women infected with both HIV and HPV and symptomatic for HIV infection with women not infected with either virus, a relative odds of 13.9 (95% confidence interval, 3.3 to 59) for squamous intraepithelial lesions was noted.

When women with Papanicolaou results typical of reactive or reparative changes only are excluded, the associations of HPV and abnormal Papanicolaou smear were still significant in the women with symptomatic HIV infection (odds ratio, 13; 95% confidence interval, 1.3 to 133). No significant associations of HPV and squamous intraepithelial lesions were noted in the asymptomatic HIV-infected or the HIV-uninfected

Table III. Association of squamous intraepithelial neoplasia with presence of HPV DNA in women with and without HIV infection and symptoms, $N = 96$

Mantel-Haenszel odds ratio, 5.8; 95% confidence interval, 1.5, 18.
*Odds ratio, 12; 95% confidence interval, 1.3 to 108.
†Odds ratio, 2.0; 95% confidence interval, 0.1 to 30.
‡Odds ratio, 4.6; 95% confidence interval, 0.8 to 28.

women, although the overall Mantel-Haenszel odds ratio was significant (5.4; 95% confidence interval, 1.4 to 18). The rates of cervical abnormality were 76% (13 of 19) for women infected with both HIV and HPV and symptomatic for HIV infection, 21% (7 of 33) for women infected with either virus or infected with both viruses but asymptomatic for HIV infection, and 11% (3 of 27) for women not infected with either virus. Women infected with both HIV and HPV and symptomatic for HIV infection were 17 times more likely to have squamous intraepithelial lesions on Papanicolaou smear than women not infected with either virus (odds ratio, 17; 95% confidence interval, 3.7 to 81).

Four women had high-grade squamous intraepithelial lesions (equivalent of grade 2 or 3 cervical intraepithelial neoplasia). All four were infected with HIV. Three of the women were infected with HPV and had symptomatic HIV infection. The fourth women was asymptomatic for HIV and did not have HPV detected.

Age and race. Sizes of individual analytic cells were small with further subgroup analyses. Significant differences in age were not noted in our population of young and middle-aged women in various comparisons: mean age in years by Papanicolaou group ($p = 0.3$), by HIV status ($p = 0.3$), by HPV status ($p = 0.5$), and by combined HIV and HPV status ($p = 0.8$).

Among symptomatic women with HIV infection, an association between abnormal cervical status and HPV was most evident among black and Hispanic women <34 years old (odds ratio, 11; 95% confidence interval, 0.8 to 148). Nonwhite and white women ≥34 years old with symptomatic HIV infection did not have a significant association of HPV with squamous intraepithelial lesions, although numbers were small (odds ratio, 4.3; 95% confidence interval, 0.2 to 108; Table IV). No white women <34 years old had symptomatic HIV infection. An overall association of HPV infection with squamous intraepithelial lesions was noted among symptomatic HIV-infected women, stratified by this combination of age and race or ethnicity (Mantel-Haenszel odds ratio, 7.2; 95% confidence interval, 1.01 to 57). This association was not explained by other measured factors, including age at first intercourse, other sexually transmitted diseases, and number of sexual partners (Table I).

Similarly, the association of HPV and HIV infections was strongest among younger black and Hispanic women (Table V). Black and Hispanic women <34 years old had a significant association of HIV and HPV infections (odds ratio, 18; 95% confidence interval, 2.0 to 161) compared with all other women (odds ratio, 2.2; 95% confidence interval, 0.7 to 6.5). A trend for highest rates of squamous intraepithelial lesions and strongest HIV and HPV correlations among Hispanic subjects was noted.

Other sexually transmitted infections. The presence of a concurrent positive genital culture for *Chlamydia* ($n = 4$) or gonorrhea ($n = 3$) was not associated with increased risk of HIV or HPV infection or with cervical

†Odds ratio, 2.2; 95% confidence interval, 0.7 to 8.8.

cytologic abnormality. None of the patients had a positive culture for herpes simplex virus. Nine patients with current evidence of syphilis were HIV seropositive, while three were HIV seronegative, representing a statistically insignificant trend toward an excess syphilis rate among HIV-infected women (Table I).

Comment

HIV, HPV, and squamous intraepithelial lesions. This study demonstrates that symptomatic HIV-infected women with HPV infection were at much higher risk for squamous intraepithelial lesions than any other subgroup.[6] This finding suggests that the immunosuppression associated with pathogenic consequences of HIV infection exacerbates HPV-mediated cervical pathogenesis.[16] Women with either HIV or HPV infection alone were at higher risk for squamous intraepithelial lesions than women without any infection, but women with both infections had an estimated relative odds of having squamous intraepithelial lesions nearly 12 times that of women with neither viral infection. The mechanism through which immunosuppression may activate and accelerate the pathogenic course of HPV infection is unclear. It is possible that immunodeficiency allows establishment of a chronic, active HPV infection, favoring the likelihood of oncogenic progression,[6, 23] or immunodeficiency may allow HPV to replicate to higher levels with more clinically aggressive lesions than in immunocompetent women, as has been noted in pregnant women.[5, 30] The ability of a local infection to persist and progress may rest on its ability to create a nurturing environment for itself by effecting depletion of Langerhans' cells and T lymphocytes in the epithelial tissue; conceivably, HPV or HIV infection could have a direct effect on Langerhans' cells, which are migrating cells that are responsible for picking up antigen and delivering it to the lymph nodes.[5, 14, 15] Additional areas for investigation include the effect of HPV type on disease progression in varying states of immune competence and the interaction of systemic and local immunologic responses in the modulation of HPV pathogenesis.

The analytic strategy in this work was designed to address three related issues: (1) to examine the association of HIV and HPV infection; (2) to see if the relationship between HPV and squamous intraepithelial lesions was modulated by either symptomatic or asymptomatic HIV infection, indicating a likely effect of immunosuppression; and (3) to see if race, age, other sexually transmitted diseases, or behavioral variables could account for, or otherwise affect, any of these virologic-clinicopathologic associations. An association of HIV and HPV was confirmed in the complete sample, but an increased rate of HPV infection was found only in the patients who were symptomatic for HIV infections (Table II). In our study, women with asymptomatic HIV infection were no more likely to be infected with HPV than were women without serologic evidence of HIV infection, although our statistical power was limited for asymptomatic seropositive women, who were comparatively underrepresented in the study sample. The principal research finding was the high risk for squamous intraepithelial lesions in the symptomatic HIV-infected women who were also infected with HPV. Finally, younger age and minority ethnic status were associated with increased risk for HIV, HPV, and squamous intraepithelial lesions. The biologic and behavioral origins of this latter observation are not known.

Since no excess risk for squamous intraepithelial lesions was noted for asymptomatic HIV-seropositive women, a threshold effect may be occurring in that only more profoundly immunosuppressed women experience increased cervical morbidity, presumably because of decreases in immunologic surveillance.[23] Alternatively, a dose-response effect is plausible with greatest risk associated with HIV and profound immunosuppression, less risk with HIV infection and less immunosuppression, compared with the baseline risk noted in a comparable population of women without HIV infection and presumably with a relatively normal immune status. Further study will be necessary to distinguish between these possibilities.

HPV-associated cervical disease should be added to the list of preventable opportunistic complications of importance in HIV-infected women. We should anticipate the possibility of an HIV-related cervical cancer epidemic among women in industrialized countries where cervical cancer rates are currently relatively low. This scenario is especially plausible if the course of HIV infection is prolonged because of antiretroviral therapy and prophylaxis for opportunistic infections, since these interventions might, in turn, permit manifestations of advanced cervical disease to occur in the setting of prolonged immunosuppression.[31, 32] Although good evidence exists for the role of both immunosuppression and HPV in cervical disease, we do not yet have the population-based data needed to fully assess the public health impact of these findings, e.g., future cervical morbidity among HIV-infected women and whether prognostic importance of the severe or intractable squamous intraepithelial lesions may be comparable to that of other opportunistic infections currently included in the acquired immunodeficiency syndrome surveillance definition. One issue immediately suggested by available data is the need for improved cervical surveillance of HIV-infected women, particularly those with HIV-related symptoms, with the Papanicolaou smear.

In developing countries with much higher baseline rates of cervical cancer, much higher frequency of other causes of immunosuppression and immune activation (malnutrition and coinfections, for example), and high prevalence of HIV in women, the concern is even greater. Papanicolaou smear screening is largely unavailable or unaffordable for poorer women in developing nations. While the findings in the present study need to be confirmed in developing countries,[12, 20] it is likely that results from such studies will ultimately reinforce the already obvious need for Papanicolaou smear screening and cervical treatment opportunities for women in developing nations as well as in many underserved communities in industrialized countries.[33]

HPV as a possible risk factor for HIV infection. Further study, of major public health importance, that should be pursued is whether HPV infection in cervical cells could facilitate HIV transmission through disruption of normal mucosal integrity or through altered local immune surveillance. Studies in small numbers of women have found evidence of decreased response of cervical lymphocytes to mitogens, decreased helper-to-suppressor T-cell ratios, and depletion of Langerhans' cells in cervical squamous epithelium infected by HPV.[5] HIV was first isolated from the cervix in 1986, and cell-associated infection is probable.[14, 15] Hence the role of

HPV in enhancing HIV infection, through the equivalent of microulcerations or areas of diminished local immune competence, should be studied prospectively in women at risk for HIV infection in the context of the many other cofactors that may facilitate HIV transmission. HPV is so common that even a modest relative risk for facilitation of HIV infection could translate into a large population-attributable risk, potentially making it an important cofactor in transmission, as has been reported for herpes simplex virus, chancroid, and syphilis, which cause larger, usually visible, but more uncommon genital ulcers.[5, 34]

Clinical policy implications. This study suggests that a number of public health policy decisions should be advocated:

1. Yearly Papanicolaou smear and gynecologic examination for women at high risk for HIV should be offered[35]; if symptomatic HIV infection or CD4+ cell counts $<200/mm^3$ occur, screen every 6 months.
2. Consider HPV-mediated cervical disease as an HIV-related opportunistic complication.
3. Offer ablative therapy for patients with high grade squamous intraepithelial lesions to avoid rapid progression of cervical disease.
4. Use state-of-the-art clinical and molecular methods to prospectively monitor high-risk women.
5. Expand Papanicolaou smear programs and appropriate therapies into the poorest communities, especially those with high HIV prevalence rates.
6. Study HPV as a potential cofactor for HIV transmission.
7. Replicate and expand the present findings, particularly in developing nations and with specific data on T-cell subsets.
8. Initiate prospective studies with improved clinical data using colposcopy.

The demographic evolution of the HIV epidemic suggests an increasing proportional representation of women.[30, 36, 37] The association of HIV, HPV, and squamous intraepithelial lesions and the continuing clinical advances in management of HIV disease all suggest that cervical disease and HPV infections are likely to become more prominent features in the clinical profile of women with HIV infection. Substantial costs in human and economic terms may be anticipated from cervical disease, particularly among women whose life spans are lengthened by treatments that do not reverse immunosuppression.

We thank Drs. Gerald H. Friedland, Lewis K. Schrager, C. Robert Horsburgh, Jr., Martha F. Rogers, Seymour L. Romney, and Leopold G. Koss for their many contributions toward initiation of this study. Substantial clinical assistance and patient referral were provided by Janice Colley, Madeline Hilton, Rafael Torres, Anita Iezza, Verna Robertson, Karen Kennedy, Marjorie Nicholson, Meera Satyadeo, Loretta Sullivan, Abigail Wolf, Diana Maude, Drs. Jane Shaw, Akinori Adachi, Neal Steigbigel, Ellie Schoenbaum, and Peter Selwyn. Ms. Carol Spitzer assisted with DNA analyses. Drs. Lutz Gissmann and Harald zur Hausen provided molecular probes. Ms. Edna Kane-Williams provided valuable editoral assistance.

Case report of laparoscopic cholecystectomy in the third trimester of pregnancy

Rita O. Pucci, MD, and Randolph W. Seed, MD, PhD
Chicago, Illinois

Laparoscopic cholecystectomy has not been reported during pregnancy. This is the first reported case of a cholecystectomy by laparoscopic technique in the third trimester of pregnancy. The patient (and her baby) had a rapid, uneventful recovery identical to that of a nonpregnant patient. (AM J OBSTET GYNECOL 1991;165:401-2.)

Key words: Laparoscopic cholecystectomy, third-trimester pregnancy

Gallstones that become symptomatic during pregnancy are usually managed conservatively, and when conservative management fails, an open cholecystectomy has been necessary. An upper midline incision is especially uncomfortable for the patient during the final weeks of pregnancy. The incidence of ventral hernias predictably increases, and the painful incision necessitates postoperative narcotics with resultant maternal pulmonary depression and fetal depression. Laparoscopic cholecystectomy avoids the incision with its resultant pain and complications and provides a great increase in the benefit/risk ratio for the patient.

Case report

A 27-year-old woman who was 31 weeks pregnant began to have right upper-quadrant pain, with nausea and vomiting, which was intermittent and was precipitated by eating. Ultrasonography of the gallbladder revealed multiple small stones with normal intrahepatic and common bile ducts. The gallbladder wall was of normal thickness.

Liver function tests and white blood cell count were normal. She was afebrile. Attempts at conservative management were unsuccessful, and the patient was unable to tolerate any diet except water for 4 days.

Surgical procedure. When the patient was under

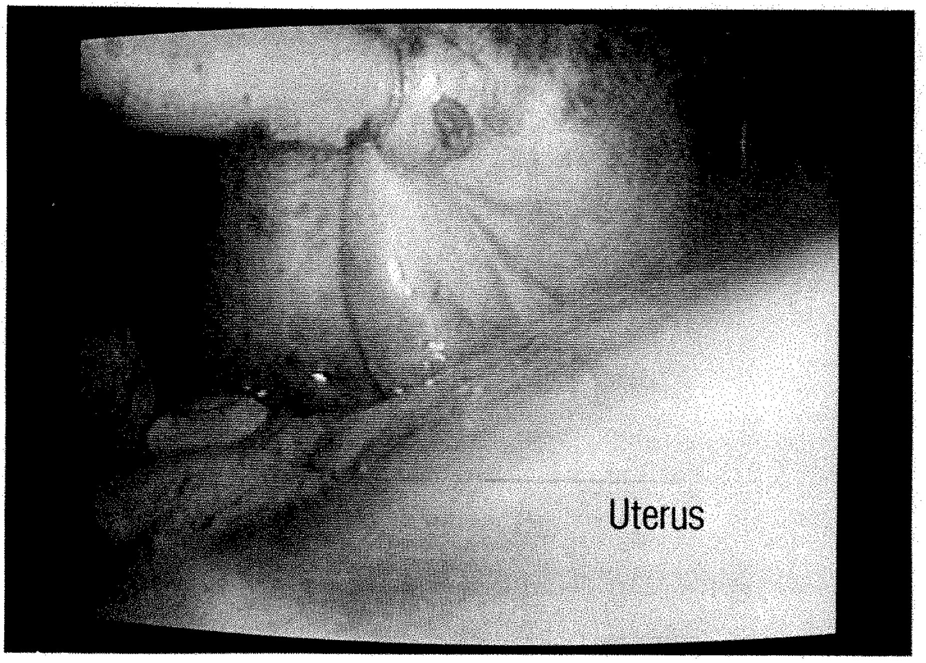

Fig. 1. Intraoperative view of gallbladder with 31-week gravid uterus in foreground.

general anesthesia, a 10 mm cannula was inserted just inferior to the umbilicus via the open (Hasson) method of laparoscopy. The patient was placed in reverse Trendelenburg position and was tilted to the left to facilitate exposure of the cystic duct and artery. A pneumoperitoneum was created with carbon dioxide to 14 mm Hg pressure. A 10 mm port with a zero-degree laparoscope was used with a camera and video monitor system. Another 10 mm port and two 5 mm ports were placed under direct vision. The gallbladder was dissected and removed by the standard, previously described method[1] (Fig. 1). The four puncture wounds were closed with subcuticular Dexon sutures.

The pathology report revealed chronic inflammation and more than 200 1 mm stones.

The patient was able to tolerate her usual diet the evening of the operation. She required only oral medication for pain and was discharged 48 hours after operation. There were no signs of fetal distress on monitoring during or after operation. A normal male infant, who weighed 6 pounds 4 ounces and who had Apgar scores of 8 and 9, was delivered by an uncomplicated, repeat low-segment cesarean section 10 weeks after the procedure.

Comment

Indications for and experience in laparoscopic cholecystectomy are rapidly increasing. Because the large abdominal incision is avoided with the laparoscopic procedure, the patient's postoperative course is markedly improved. Pain is controlled by oral medications, patients are able to eat a normal diet the same day, and most patients go home within 24 hours and are back at work within 1 week. In pregnant patients laparoscopic cholecystectomy has additional advantages. Fetal depression from intramuscular narcotics is eliminated, because postoperative pain is minimal. The potential atelectasis from hypoventilation that results from the combination of intraabdominal mass effect (gravid uterus) and incisional pain is nil.

The major complications related to an abdominal incision (wound infection, wound disruption, and ventral hernia), that occur especially during the last 2 months of pregnancy become moot.

Because this patient was out of bed within 8 hours after operation, pulmonary embolism predictably became a very remote possibility.

In this case return to a full diet in 8 hours eliminated any nutritional stress to the baby. In our experience of >100 consecutive laparoscopic cholecystectomies, 96% of patients have been able to eat a normal diet the same day.

It has been stated[2] that pregnancy is an absolute contraindication for laparoscopic cholecystectomy. No reasons have been given. An open approach to inserting the laparoscope avoids inadvertent injury to the uterus or intrabdominal contents. The other ports can then be inserted under direct visual control.

The issue of adequate visualization of biliary structures is always the determining factor for safe completion of the procedure. At 31 weeks' gestation, in this case at least, there was no difficulty, and we would not expect this to be an exception.

Intraoperative serial monitoring of arterial blood gas values in our laparoscopic cholecystectomy patients has shown little effect on P_{CO_2} or arterial pH and no effect on P_{O_2} or bicarbonate. There was no noticeable intraoperative or postoperative effect of increased abdominal pressure that resulted from carbon dioxide insufflation to 14 mm Hg, but long-term results are not available.

We believe that pregnancy is not a contraindication to a laparoscopic cholecystectomy, and the procedure provides marked benefits for the patient who needs removal of the gallbladder during pregnancy.

Psychosocial support for maternal stress during pregnancy: Effect on birth weight

Alan D. Rothberg, MB, BCh, and Bernice Lits, MA
Johannesburg, South Africa

In a previous study we showed that moderate to severe stress during pregnancy was inversely related to infant birth weight. Using the same criteria for stress (according to the Social Readjustment Rating Scale of Holmes and Rahe), we studied 86 white mothers with singleton pregnancies and with no known medical or obstetric risk factors for reduced birth weight. After strict randomization, data were analyzed for 43 mothers who received psychosocial support between enrollment at ±20 weeks and delivery at ±38 weeks and for 43 control mothers who received standard care at the antenatal clinic. In the supported group seven infants weighed <3000 gm at birth versus 18 control infants ($p = 0.008$), and analysis revealed that this effect was more the result of improved intrauterine growth than of prolongation of pregnancy. These findings are of little clinical relevance as far as the neonate is concerned, but they do indicate that psychosocial support has a significant effect on birth weight. It is possible that previous studies that have looked only for an effect on low- or very-low-birth-weight rates might have missed this clinically measurable benefit of counseling. (AM J OBSTET GYNECOL 1991;165:403-7.)

Key words: Psychosocial support, pregnancy, birth weight

A relationship between major life events and low birth weight (<2500 gm) has been described by several authors.[1-3] This led us to a preliminary study in 1985,[4] in which a group of 118 mothers who were delivered prematurely at the Johannesburg Hospital were shown to have an excess of moderate to severe stressors as identified by the Social Readjustment Rating Scale of Holmes and Rahe.[5] Our initial study was followed by a larger retrospective study of 535 mothers delivered at the same hospitals; moderate to severe stress factors were identified in 48% of the mothers, and a significant, inverse relationship was observed between cumulative stress score and birth weight.[6] Having thus confirmed an interaction between stress and birth weight in our local population, we faced the question whether stressed mothers attending the antenatal clinic would benefit from psychosocial support and whether such support would influence birth weight or gestational age. While descriptive studies have demonstrated the interaction between psychosocial stress and birth weight,[1-3, 7] as indicated in a recent overview,[8] no prospective, controlled trial has specifically evaluated the effects of intervention in mothers enrolled on the basis of psychosocial stress.

Subjects and methods

Data from the previous study[6] were used to determine sample size for this randomized, controlled study of support for mothers suffering from moderate to severe stress during pregnancy. Analysis of data from the previous study[6] indicated that a stress effect approached significance when a weight cutoff of 3000 gm was used; 25% of the 280 babies born to nonstressed mothers weighed <3000 gm versus 35% of the 255 babies born to those with stress. On the basis of these figures, the prospective study was designed with a minimum sample of 86 subjects required to determine whether intervention could achieve a 50% reduction in the number of babies weighing <3000 gm.

Mothers of singleton pregnancies were eligible for enrollment between the eighteenth and twenty-fifth weeks of pregnancy if they were free of medical or obstetric problems known to be associated with prematurity or low birth weight (LBW). In keeping with the objective of eliminating as many known causes of LBW (<2500 gm) as possible, the study was confined to white mothers; this was because of the known association between lower birth weight and black race.[9] As in the preliminary study,[6] stress was defined as any factor scoring ≥39 on the Social Readjustment Rating Scale[5] (Table I) and occurring within the 6 to 12 months before enrollment. Individual scores were added together, and analysis was therefore in terms of the cumulative stress score.

Mothers were interviewed at the antenatal clinic by one of the authors (B.L.). Those eligible for entry on the basis of a history of stress, and willing to participate in the study, were randomized into support or control

Separation from baby's father	65
Divorce	73
Death of baby's father	100

groups. Before randomization all mothers signed an informed consent form that indicated that they might or might not be selected for additional interviews or counseling sessions with a social worker involved in the study. Randomization was simple (unstratified), by means of sealed envelopes containing a green or pink slip of paper, indicating assignment to support or control groups, respectively. Mothers in the support group entered into a regular, individualized, client-centered relationship with one of two social workers contracted to the study. Both social workers were skilled counselors with experience in gestational support and crisis intervention. Support consisted of at least 20 minutes with the social worker at the time of each antenatal clinic visit. When mothers felt unable to wait for the social worker on a clinic day, arrangements were made to make up the missed visit, or for the social worker to have a 10- to 20-minute telephone counseling session with the subject. The psychosocial support was directed toward dealing with the stress factor(s) that had warranted enrollment in the study, assisting with problems in the home or work situation, and encouraging mothers to comply with instructions and advice of the antenatal clinic staff. Control mothers were treated according to the usual protocols of the antenatal clinic; those personnel, while obviously aware of the existence of our study, were largely unaware of the personal problems of the mothers.

Additional data collected in every case included maternal age, obstetric history, marital status, and number of clinic visits after enrollment. Smoking history was recorded and, while we did not include a specific antismoking program in the study design, mothers were exposed to the standard information in the form of educational posters and pamphlets at the clinic. At the time of delivery, birth weight and length were recorded for every baby by a labor ward staff member who was unaware of the subject's group assignment, and gestational age was assessed by one of the authors (A.D.R.) according to the Ballard score.[10] Mothers completing the study were interviewed within 2 weeks of delivery to assess the value of support for the study mothers and perceptions regarding need for support on the part of controls.

Statistical analysis was by means of t tests for normally distributed data or otherwise by the Mann-Whitney test; Fisher's exact or χ^2 tests were used to compare differences in proportions between groups. Interactive multiple linear regression analysis was used to explore the relationship between variables.

The study was approved by the University Committee for Research on Human Subjects.

Results

To be assured of the minimum sample size required (86 subjects, 43 per group), i.e., allowing for dropouts, abortions, and transfer of mothers to other hospitals, 104 subjects were enrolled between May 1989 and August 1990. Eight subjects were excluded (two aborted shortly after enrollment, two developed medical problems, twins were diagnosed in one, three transferred to other medical centers). Excluded subjects within each of these categories were equally distributed between support and control groups. Data collection was stopped when 43 subjects in each group had completed the study; however, the four remaining mothers in the support group continued to receive counseling until delivery, and the six remaining in the control group continued with routine care.

Table II shows the characteristics of the study population and also demonstrates how closely the present group of 86 resembles the 255 stressed mothers studied in 1985[6] in terms of maternal age, cumulative stress score, birth weight, and LBW rate. Mothers were entered into the present study at 20.7 ± 2.6 weeks of pregnancy (mean ± SD).

Interactive regression analysis of data for the total group showed that psychosocial support, gravidity, and smoking were significant determinants of birth weight, together accounting for 14.8% of the variance. Infant sex, maternal age, marital status, and previous stillbirth or abortion were not important in this model.

When the data were analyzed according to support and control groups, there was a significant reduction in the number of infants weighing <3000 gm in the supported group (7 of 43 vs 18 of 43; $p = 0.008$; odds ratio, 0.29; 95% confidence interval, 0.12 to 0.74); however, the number of LBW babies was similar in both groups (six of 43 in the supported group vs five of 43 in controls). While there was a trend toward a higher prematurity rate in the control mothers, the difference was not significant (20.5% of control mothers delivered before 37 completed weeks vs 10.8% of those who received support, $p = 0.2$). The above-mentioned weight and gestational age data suggest that psychosocial support had a greater effect on fetal weight than on du-

Table II. Major similarities between study population and 1985 group of stressed mothers[6]

	Present study (n = 86)	*Retrospective study (1985)[6] (n = 255)*
Maternal age (yr, mean ± SD)	24.5 ± 5.4	24.5 ± 5.2
Cumulative stress score (mean ± SD)	74 ± 33	72 ± 35
Birth weight (gm, mean ± SD)	3164 ± 668	3147 ± 580
LBW rate (%)	12.8	12.9

ration of pregnancy, and neonatal length and weight-to-length ratios appear to confirm this postulate. Mean neonatal length (±SD) was similar for both groups (49.3 ± 2.1 cm for control infants vs 50.0 ± 2.8 cm for those of supported mothers), while weight-to-length ratios were significantly different in the two groups (30% of controls weighed <55 gm/cm length vs 11.4% born to supported mothers; $p = 0.045$). The change in the distribution of birth weight between the groups of infants is shown in Table III.

Two neonates from the supported group required admission to the neonatal intensive care area for ventilatory support. Both were of very low birth weight and one died (875 gm). One very-low-birth-weight neonate from the control group required admission to the intensive care area for management of hypoglycemia. No neonatal problems of note were encountered in the remaining 83 infants.

Characteristics of the two groups of mothers and infants are shown in Table IV. Of particular note are the following: relatively high percentage of smokers in both groups; mean birth weight difference of 101 gm between control and supported groups; and eight or more visits to the antenatal clinic for all mothers, with supported mothers receiving seven or more sessions with the social worker in the ±18 weeks between enrollment and delivery. The significantly greater number of women with previous abortions or stillbirths in the supported group is a chance finding but even if significant would probably have acted to increase and not diminish the risk of lower birth weight in this group.[11] The effect of counseling appeared to be independent of any effect on maternal smoking; similar numbers of supported and control mothers modified their smoking habits during the study.

In Table V, mothers of infants weighing <3000 gm are compared according to support or control status. Because of the small number of infants in the support group, most of the differences are not significant; however, it would appear that the seven mothers who were "unresponsive" to support were more likely to be older, multiparous smokers who, despite a poor obstetric history, were infrequent attenders of the antenatal clinic.

Fifty-one percent of supported mothers rated the sessions with the social worker as being very helpful, 40% found the support to be of some help, 5% did not benefit at all, and 4% did not complete the questionnaire. In the control group, 58% felt that support was not needed, 30% would have appreciated some help, and 12% did not return the questionnaire. No mothers in the control group were referred for counseling by antenatal clinic staff.

Table III. Birth weight distribution of infant groups

Birth weight (gm)	*Supported (n = 43)*	*Control (n = 43)*
<2000	2	2
2000-2499	4	3
2500-2999	1	13
3000-3499	22	11
3500-3999	11	11
≥4000	3	3

Comment

Interactions between maternal behavior, inadequate social support systems, and personal maternal characteristics have been described which might lead to uteroplacental problems and premature labor.[12] In the proposed model stress leads to catecholamine release, decreased placental function, and uterine irritability. While premature labor may be the end product of stress, it is clear that uteroplacental problems might also interfere with fetal nutrition and growth. Several authors have confirmed these effects of stress in retrospective[1-4, 6] and prospective[7] studies, with most implying or concluding that randomized, controlled trials are required to establish whether the deleterious effects can be reversed by psychosocial support during pregnancy.

Elbourne[8] has commented on the data from 12 relevant controlled trials, which have been included in the Oxford Database of Perinatal Trials. In terms of the outcome measures applicable to the present study, the meta-analysis reveals that social support during pregnancy influences neither the LBW rate nor the preterm delivery rate (typical overall odds ratios, 0.89 and 0.99; 95% confidence intervals, 0.76 to 1.05 and 0.84 to 1.17, respectively).

This study differed from those reviewed by El-

bourne[8] in that we studied only white mothers subjected to moderate to severe psychosocial stress. In accordance with the meta-analysis, LBW and prematurity rates were not affected by support during pregnancy, but there was a highly significant effect on the number of infants weighing <3000 gm. Furthermore, this effect of support appeared to be due to improved intrauterine growth rather than prolongation of pregnancy. These results are reminiscent of those of Olds et al.,[13] who found that in a subset of smokers and young adolescents, intervention improved birth weight and length of gestation, but not in the lowest ranges. However, in contrast to one of the conclusions in a subsequent review by Olds and Kitzman,[14] our results were obtained by means of psychosocial support, but without specific attention to alteration of adverse behavior. Support in this study was directed toward dealing with the stress factor(s) that had warranted enrollment, and while the social workers were instructed to provide help or advice with additional domestic, occupational, or health-related problems, they were only infrequently called on to do so.

The support provided to stressed mothers in this study was rated as being very or moderately helpful by 91% of the group. In the control group 58% of mothers questioned after delivery were of the opinion that support would not have helped them, while 30% would have appreciated some assistance with their problems. In this study we did not assess other subjective aspects such as attitudes toward the pregnancy, confidence levels, or relationships with family or medical staff, preferring to use objective measurements to evaluate the effects of intervention. In this regard we did analyze the instrumental or operative delivery rates in the two groups, and, in agreement with the results of the meta-analysis,[8] found that support did not have any effect.

In evaluating the effects of a variety of stressors during pregnancy, most studies use LBW or very LBW as end points.[1-4, 7, 8] These are important measures because LBW and very LBW, whether because of preterm birth or intrauterine growth retardation, affect neonatal and postneonatal mortality, as well as subsequent infant and childhood morbidity.[15] We cannot question the rationale for assessing stress or intervention effects in terms of LBW or very LBW rates; however, we have shown that by doing so one might miss other measures of outcome, in this case the number of births between 2500 gm and 3500 gm. The significant effect of psychosocial counseling in increasing birth weight to above 3000 gm is of little consequence in terms of neonatal outcome but shows far more conclusively than before[8] that support during pregnancy has a clinically measurable effect.

Transvaginal removal of ovaries with endoloop sutures at the time of transvaginal hysterectomy

Mitchel S. Hoffman, MD
Tampa, Florida

Twenty patients were evaluated for possible oophorectomy during transvaginal hysterectomy. Of 40 ovaries, nine were removed with a standard clamp technique. Twenty-two ovaries could not be removed by the clamp technique but were successfully removed with endoloop sutures. Safe transvaginal removal was not thought to be possible for the remaining nine ovaries. (AM J OBSTET GYNECOL 1991;165:407-8.)

Key words: Oophorectomy, transvaginal; suture, endoloop

The purpose of this study was to evaluate the feasibility and safety of transvaginal oophorectomy by the endoloop suture at the time of transvaginal hysterectomy.

Material and methods

This was a prospective observational study. Ovarian removal by the standard clamp technique was performed when possible. If the standard technique was not feasible but the ovaries appeared to be reasonably accessible, then removal with the endoloop suture (size 0 plain gut ligature; Ethicon Inc., West Germany) was attempted. When the uterus had been removed, each ovary was grasped with a long Babcock clamp and was pulled with moderate traction into the vagina. An endoloop suture was then brought around the Babcock and was secured above the ovary at the origin of the mesovarium. A second endoloop suture was placed close to the first. The ovary was then excised under direct vision and with right-angle scissors holding the endoloop sutures.

Results

From July 1 to Dec. 21, 1990, 26 consecutive patients were eligible for this study. Six patients were excluded from the study after they declined oophorectomy; this resulted in a total of 20 patients for analysis. The mean age of the 20 patients was 50 years; the age range was 38 to 72 years. The mean parity was 2.8, with a range of 0 to 8. Five of the patients were morbidly obese. Eight patients had undergone genitourinary surgery. The primary diagnosis was symptomatic pelvic relaxation in five patients, atypical endometrial hyperplasia in three patients, grade 1 endometrial carcinoma in three patients, uterine leiomyomas in five patients, grade 3 cervical intraepithelial neoplasia in three patients, and stage IA squamous cell carcinoma of the cervix in one patient.

In four of the 20 patients bilateral oophorectomy was successfully accomplished with the clamp technique. In 10 patients bilateral oophorectomy could not be accomplished by the standard clamp technique but was successfully accomplished with the endoloop technique. In one patient one ovary was successfully removed by the clamp technique and the other ovary was removed with the endoloop technique but the other ovary was not thought to be accessible for removal. In the remaining four patients safe transvaginal removal of the ovaries was not thought to be possible and was not attempted. In the 10 patients who underwent transvaginal endoloop oophorectomy, the mean operative time (for bilateral oophorectomy) was 18 minutes, with a range of 15 to 30 minutes. The estimated blood loss for all 10 patients ranged from 0 to 5 ml.

Thirty-one ovaries were removed in this study, and 22 of these were removed with the endoloop technique. If the two largest dimensions are considered, the mean size of the ovaries removed was 3.3 × 2 cm, with a range of 1.5 to 6 × 1 to 4 cm. Of the 31 ovaries removed, four had benign pathologic findings. These findings included one fibroma, one hyperplastic stromal nodule, and two ovaries with extensive hyperthecosis. These ovaries were removed by the endoloop technique. The hyperthecotic ovaries were enlarged, and it was actually necessary to morcellate them to accurately visualize the pedicle of the mesovarium where the endoloop sutures had been placed.

There were no intraoperative complications. During the study five endoloop sutures were either broken or placed incorrectly and had to be immediately replaced. Five patients experienced postoperative febrile morbidity that resolved with intravenous antibiotics. These five patients included three who had undergone the endoloop technique, one who had undergone the clamp technique, and one in whom oophorectomy had not been attempted.

Comment

The purpose of this study was to evaluate the feasibility and safety of transvaginal oophorectomy via the endoloop technique at the time of transvaginal hysterectomy in those patients in whom the standard clamp technique was judged not feasible. Of the 40 ovaries evaluable for removal in this study, only nine were successfully removed with the standard clamp technique.[1, 2] The possibility of selection bias cannot be denied, except to say that every effort was made to avoid it. Twenty-two of the 31 ovaries thought not to be removable by the standard clamp technique were removed successfully with the endoloop technique. Also, the endoloop technique required less space and provided better visualization of the mesovarium, which may have allowed more accurate and complete removal of the ovary. Morcellation of the ovaries in one case added to visualization of the mesovarium. Morcellation of the ovaries should not be undertaken in the presence of a suspected neoplasm. The results of this study suggest that transvaginal removal of ovaries that otherwise cannot be removed by the standard clamp technique is safe and feasible in the majority of patients with the endoloop technique described.

Improving disclosure of smoking by pregnant women

Patricia Dolan Mullen, DrPH,[a] Joseph P. Carbonari, EdD,[b] Ellen R. Tabak, PhD,[a] and Marianna C. Glenday, MPH[a]

Houston, Texas

Smoking is a major modifiable risk factor in pregnancy, and low-cost interventions have been developed and tested in diverse populations of pregnant smokers. Successful intervention depends on identification, however, and nondisclosure can be a problem. This randomized study compared rates of disclosure with two response formats—multiple choice, in which the patient is able to describe herself as having "cut down," and the usual history question, "Do you smoke?," in which she is forced to answer simply "yes" or "no." Each format was tested in both oral and written channels with a multiethnic adult prenatal population ($n = 1078$) entering care in a multispecialty group. Study results indicate that the multiple choice question improved disclosure, regardless of channel (oral versus written), by 40%. This effect was observed across racial and ethnic groups. Biochemical tests of urine samples from reported nonsmokers indicated smoking in only 3%. Eleven percent of the "nonsmokers" in the experimental groups refused consent for the urine test, however, and many of these were probably smokers. (Am J Obstet Gynecol 1991;165:409-13.)

Key words: Prenatal risk assessment, prenatal history taking, validation of self-reported smoking status

Smoking is a major modifiable risk factor in pregnancy, and recent randomized trials of low-cost counseling and self-help material tailored to pregnancy have documented increased cessation in diverse populations of pregnant smokers.[1-3] Clinically significant decreases in rates of smoking, 12 to 14 percentage points over usual care, have been achieved. Application of these intervention methods in obstetric practices, however, depends on effectively identifying smokers.

Most physicians now ask about patients' smoking habits,[4,5] and as a practical matter they must rely on simple verbal inquiry. Biochemical validation is costly, and several of the inexpensive tests are subject to substantial error in classifying individuals. Thus it is of importance that the results of recent studies evaluating the veracity of responses to verbal inquiry indicate a wide range in nondisclosure rates, from 4% to 45%.[6-9] The higher rates occur in contexts where patients perceive smoking as especially undesirable.[10] This is a likely perception for women in prenatal care, as awareness of the health risks to the fetus increases in the population.

The study reported here originated in a population-based study of a prenatal smoking cessation intervention in a health maintenance organization.[2] The investigators drew on social science methods for obtaining sensitive information[11] to develop an effective question for identifying smokers. The resulting question appeared to be advantageous, but it was not tested experimentally against alternatives. In this paper we report the results of a randomized study comparing the relative effectiveness of practical methods for identifying pregnant smokers against the traditional methods for eliciting smoking status.

Material and methods

Design. The study used a randomized, fully crossed 2×2 factorial design with two response formats ("yes" or "no" and multiple choice) and two channels of questioning (oral and written) and applied the four combinations to all eligible women on their first prenatal visit. Research literature from sociology and the previous clinical trial experience suggested that channel and response format are crucial dimensions in eliciting sensitive information. The same neutrally worded question was used in the four experimental conditions (Fig. 1).

The usual history question was represented as the dichotomous response format, whether through an oral or written channel. We selected the multiple choice format (Fig. 1) because of its success in the pilot study and its options ("I smoke every once in a while" and ". . . I have cut down since becoming pregnant") that offer the woman a means of portraying herself in a more positive light. Multiple choice may be better suited for

*Of these, 121 did not consent for use of their prenatal form.

†Maternal index score ranges from 0 to 6 and is the number of problems in this pregnancy: chronic hypertension, diabetes, heart disease, hemorrhage, pregnancy-induced hypertension, pulmonary disease.

‡Fetal-infant index score ranges from 0 to 8 and is the number of problems in previous pregnancy: mental handicap, neonatal death, neurologic disorder, prematurity, small for gestational age, sudden infant death syndrome, spontaneous abortion or ectopic pregnancy, stillbirth.

written delivery, although in a pretest all women were easily able to recall the response options after oral presentation.

The logical order of the multiple choice options is as given in Fig. 1. Although it is theoretically possible to reverse the present order, beginning the list with "I don't smoke" might program the woman's thinking to select the first and easiest alternative, thereby interfering with her consideration of a different and more honest answer. The reading level of the question was fifth grade, as rated on the Flesch-Kincaid Readability Test.

In all four experimental conditions, we combined the smoking history question with other questions about personal behavior to form a presumed gradient of sensitivity. Thus use of automobile safety belts preceded the smoking question, and questions about alcohol and illicit drugs followed it. The format of the alcohol question was always identical to the smoking question to maintain a plausible flow of questions, and the ordering of the four questions in each set was constant.

Within each of the four clinic sites all women seen on a given day were randomly assigned to one of the four experimental conditions. This clustering of one to 10 women who might be seen in one day's intake was to assure integrity of application and to fit the project into the clinic routine as smoothly as possible.

Population. All women ≥18 years old were eligible for the study if they were able to speak and read English, were free of mental and sensory handicaps, and made their first prenatal visit at one of four multispecialty group satellite clinic locations during a 17-month period (September 1988 through February 1990). Ability to read and speak English was established with a single question, "Do you speak and read English?" We excluded potential subjects if a sensory handicap or evidence of mental retardation or mental illness was found in the course of the history and education session with the nurse educator.

Procedures. The experiment was a part of the first visit for prenatal care after pregnancy had been confirmed. Prenatal intake visits were scheduled on a single day of the week. At this visit all women saw a specially trained nurse educator to give their medical history, discuss clinic procedures, and receive advice about diet, smoking, alcohol and other drug use, and warning signs of problems in the pregnancy. The sessions lasted approximately 40 minutes. The patient then gave urine and blood samples. Over the course of the study, 19 nurse educators conducted sessions in the four clinics, with a range of two to 203 sessions per nurse, with five nurses doing fewer than 25 sessions and four doing 99 or more each.

The experimental questions were embedded in the history questions and were substituted for usual ques-

tions about smoking, alcohol, and illicit drugs. The history already contained both oral and written components, so the experimental variation was easily integrated.

Self-report of sensitive behavior can be influenced by the knowledge that an objective measure of the same behavior will be used to verify the report.[12] Thus only after the history and education components of the session were completed and before being directed to the laboratory were all eligible women asked to give written consent for copies of their prenatal history forms to be used anonymously by the university-based researchers. Those women who said they were not smoking currently also were asked for written consent to conduct an additional test on the urine sample they would be giving at the laboratory. The same procedure was used for all four groups so that knowledge of the test did not influence response to the smoking history questions. The test was described as (1) anonymous and (2) "a test for by-products of exposure to cigarette smoke in pregnant women." This procedure was approved by the human subjects protection committees at the university and the clinic. Except for a study number, identifying information was removed from the history forms and urine samples before being transferred to the researchers.

Validation of self-report. The urine samples of all women who reported nonsmoking and who gave consent for the test were analyzed for presence of a major nicotine metabolite, cotinine. This assessment was by enzyme immunoassay,[13] with the laboratory blinded as to subjects' group assignment. The sensitivity of this test is 93%, with a specificity of 95% for serum in pregnant women.[14] All recommended precautions were observed in labeling, handling, storing, and shipping the urine samples. Forty-eight samples were cross-validated with liquid gas chromatography analysis, a more sensitive and specific procedure.[15, 16] There was 100% agreement on both positive and negative samples, with a cutoff of ≥50 ng/ml.

Analysis. We analyzed the data by means of a logistic regression model. The primary dependent variable was self-reported smoking on either the dichotomous question or a "yes" response to any of the first three categories on the multiple choice question. The independent variables were response format, dichotomous or multiple choice, and channel of question, oral or written. Interaction of the two also was tested.

An alternative measure of the extent of smoking disclosure was developed from the giving or withholding of informed consent to allow a urine analysis. Those patients who said they were not smoking but refused to give consent were classified as disclosures. This measure excluded those patients who admitted to smoking and thus potentially identified another population, i.e., those who would not disclose smoking behavior regardless of the format and channel of questioning.

Results

Of 1206 pregnant women seen for care during the study period, 1078 (89.4%) were eligible for the study. The two major reasons for ineligibility were being <18 years old (37%) and not speaking and reading English (24%). Sociodemographic and obstetric history profiles are given for each experimental group and for the total sample, excluding 121 women who did not give consent for use of their prenatal history form (Table I). The sample can be described as representing white, black, and hispanic ethnic and racial groups, married, having a mean age of 28 years, with one or fewer living children, and with the large majority having no maternal or previous fetal or infant health problems. The nurses frequently omitted questions about maternal and paternal schooling, and thus these characteristics are not known. Random assignment appears to have yielded equivalent groups on measured variables.

The results of the analysis regarding self-reported smoking showed disclosure was affected by format rather than channel of questioning. More women reported smoking as a function of being asked using the multiple choice format than being asked using the dichotomous format ($p < 0.014$). The channel of questioning, oral or written, did not result in different levels of self report, and there was no interaction of format and channel.

Table II provides the frequencies of reported smoking related to format. The multiple choice format elicited a five percentage point higher (13.96% versus 9.19%) positive smoking response (odds ratio, 1.60; 95% confidence interval, 1.10 to 2.33). There were no differences among ethnic or racial groups. Within the multiple choice question, distribution of responses indicating current smoking was as follows: cut back for the pregnancy, 61.6%; smoke every once in a while, 21.9%; and smoke the same amount as before pregnancy, 16.4%.

The second phase of the study tested withholding of consent for the additional urine test as a measure of nondisclosure in response to the questions about smoking. The same categorical model was applied to the urine consent measure for 954 self-reported nonsmokers. No interaction effects or main effects were found for format and channel. The overall rate of nonconsent was 11.0%. The urine test results indicated smoking in fewer than 3% of those who gave consent for the test.

Comment

The 40% improvement in disclosure found in this study is statistically and clinically significant. It was observed across three ethnic and racial groups in a clinical context where patients gave their responses without being influenced by knowledge of the research. Also, the questions were tested by interviewers with a range of backgrounds and interviewing skills.

The lack of difference between the oral and written formats suggests that the written form could be used by any health care provider. Because the "demand" to give a desirable answer to a physician may be higher than to a nurse and because of the time savings, we recommend use of the written format.

It is probable that the current association of urine testing with screening for illicit drugs produced some of the nonconsent for the urine tests. Nevertheless, many of the 11% who did not give consent for the urine test undoubtedly are smokers. This group of unidentified smokers suggests the limits on the sensitivity of the history-taking method tested here.

The difference in disclosure that we found, however, would mean that over 55,000 additional pregnant smokers could be identified annually by simple changes in history taking. These identification methods did not elicit a defensive reaction by the woman, as would other means such as nonvoluntary biochemical testing, and the multiple choice question may give more information about the patient's smoking habit. The response option most frequently selected by current smokers, having cut down since the pregnancy began, appears to reflect the true behavior in many women early in pregnancy. For this group and others who had not really cut down, this response offers a means of displaying a partially positive image to the prenatal caregiver. Thus the additional women identified are expected to be as amenable to intervention as others. Such intervention should be a high priority in prenatal care not only to help prevent low birth weight[17, 18] but also to reduce exposure to environmental smoke by infants[19, 20] and to reduce smoking among younger women whose rates of smoking make them a high priority target for smoking cessation efforts.[21-24]

We acknowledge the contributions of Mary Ann Richardson and Carol Busby of the Center for Health Promotion Research and Development to project management and manuscript development. From the Kelsey-Seybold Clinics the following individuals supported the conduct of the project: Dr. George Coale, Elene Heyer, Carolyn Hayball, Barbara Erwin, Ms. Vivian Malone, Rene Anderson, Pamela Andrews, Anna Bean, Debra Carpenter, Lisa Kelley, Ruthann Koza, Barbara Krohn, Jeanne Lauda, Anna Perez, and other nurse educators. Dr. Jeffrey Wilkins, West Los Angeles Veterans Administration Medical Center, conducted the urine validation tests, and the Clinical Biochemistry Branch, Centers for Disease Control, contributed the biochemical analyses (Dr. Francis W. Spierto, Supervisory Research Chemist).

Thrombotic thrombocytopenic purpura first seen as massive vaginal necrosis

Deborah C. Gallup, MD,[a] Thomas E. Nolan, MD,[a] David Martin, PhD, MD,[b]
Donald G. Gallup, MD,[a] and Donald M. Sherline, MD[a]
Augusta, Georgia

Thrombotic thrombocytopenic purpura is a hematologic disorder that affects the microcirculation. A 38-year-old woman was first seen with fever, thrombocytopenia, and vaginal bleeding. Pelvic examination revealed massive vaginal necrosis. Hematology consultation resulted in agreement with the diagnosis of thrombotic thrombocytopenic purpura. This is the first reported case of thrombotic thrombocytopenic purpura first seen as vaginal necrosis of which we are aware. (Am J Obstet Gynecol 1991;165:413-5.)

Key words: Thrombotic thrombocytopenic purpura, vaginal necrosis, cocaine

Thrombotic thrombocytopenic purpura is a rare, life-threatening disorder characterized by the pentad of fever, microangiopathic hemolytic anemia, thrombocytopenia, neurologic symptoms, and renal dysfunction. The pathogenesis of thrombotic thrombocytopenic purpura, however, remains unclear. In >90% of cases, purpura is the initial manifestation and may be associated with epistaxis, hematuria, gastrointestinal hemorrhage, menorrhagia, and hemoptysis. Fever is noted in all cases.[1, 2] The following represents the first known case of thrombotic thrombocytopenic purpura first seen as massive vaginal necrosis of which we are aware.

Case report

A 38-year-old gravida 3, para 3 black woman went to a local emergency room with a 3-day history of fever, chills, abdominal pain, vaginal bleeding, and discharge. Examination was remarkable only for mild abdominal tenderness. Pelvic examination was refused because of discomfort. Vital signs were stable. Laboratory data revealed a thrombocytopenia of 42,000/mm^3. She refused admission. The next day her symptoms worsened and she returned to the emer-

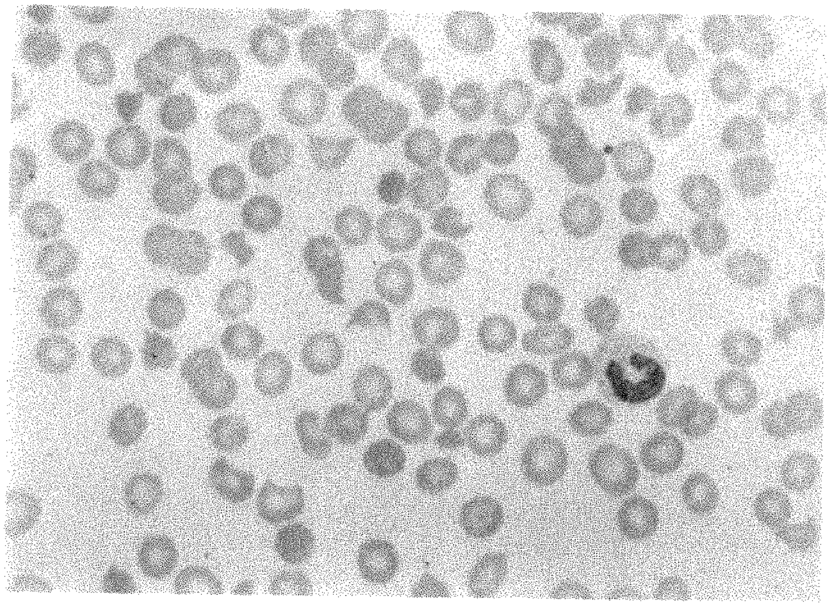

Fig. 1. Peripheral blood smear shows red blood cell fragmentation.

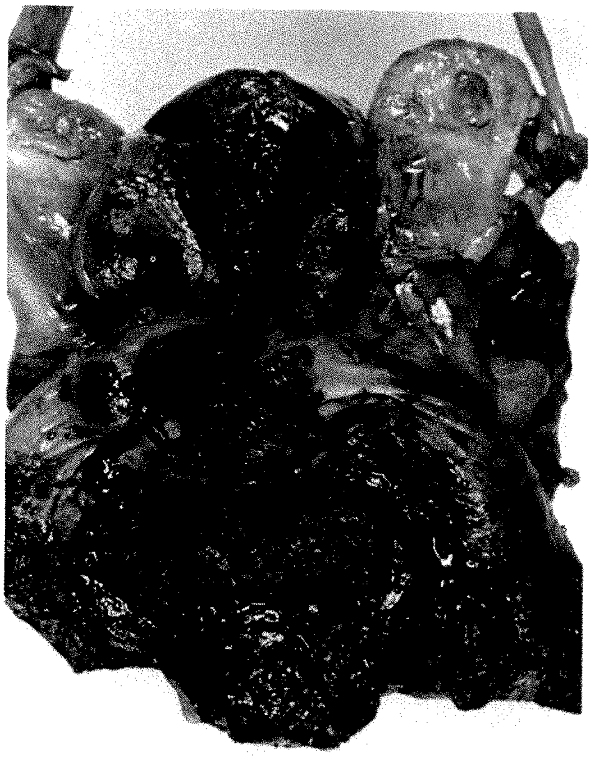

Fig. 2. Extensive necrosis and hemorrhage of the vagina.

gency room. Examination results were unchanged. White cell count was within normal limits. Platelet count was 8000/mm^3 and the hemoglobin value had dropped from 13.4 to 8.6 gm/dl. The coagulation profiles were normal. Blood urea nitrogen and creatinine values had risen from normal to 66 mg/dl and 3.2 mg/dl, respectively. The drug screen was positive for cocaine. She was admitted to the local hospital with the presumptive diagnosis of pelvic inflammatory disease and sepsis complicated by disseminated intravascular coagulation.

Treatment was begun with platelet and blood transfusions and antibiotics (clindamycin, aztreonam, and ceftriaxone sodium). Computed tomography scan of the abdomen showed an enlarged uterus with a bacteriogenic gas pattern, suspicious of uterine abscess versus degenerative malignant changes. Cultures of blood, urine, and cervix were without growth. Hematemesis developed 48 hours after admission and she was transferred to the Medical College of Georgia.

Pelvic examination at the time of admission to the Medical College of Georgia revealed proximal vaginal necrosis with sloughing of tissue. Examination after induction of anesthesia, dilatation and curettage, and biopsies were done for a more thorough evaluation. A circumferential vaginal lesion extended anteriorly throughout the entire length of the vagina with minimal posterior involvement. The tissue was dark red, nonnodular and friable. No cervical lesions were noted. The uterus sounded to 8 cm. Histopathologic diagnoses included vaginal necrotic debris, chronic cervicitis with acute hemorrhage, and proliferative endometrium.

Hematology consultation was obtained. A diagnosis of thrombotic thrombocytopenic purpura was made on the basis of the peripheral blood smear (Fig. 1), thrombocytopenia, fluctuating mental status, renal dysfunction, and fever. Treatment was begun with four units of fresh frozen plasma every 6 hours until plasma exchange could be instituted the next morning. That evening, 2 days after admission, she became lethargic, apneic, and died of a cardiopulmonary arrest.

At autopsy, numerous petechial hemorrhages of the

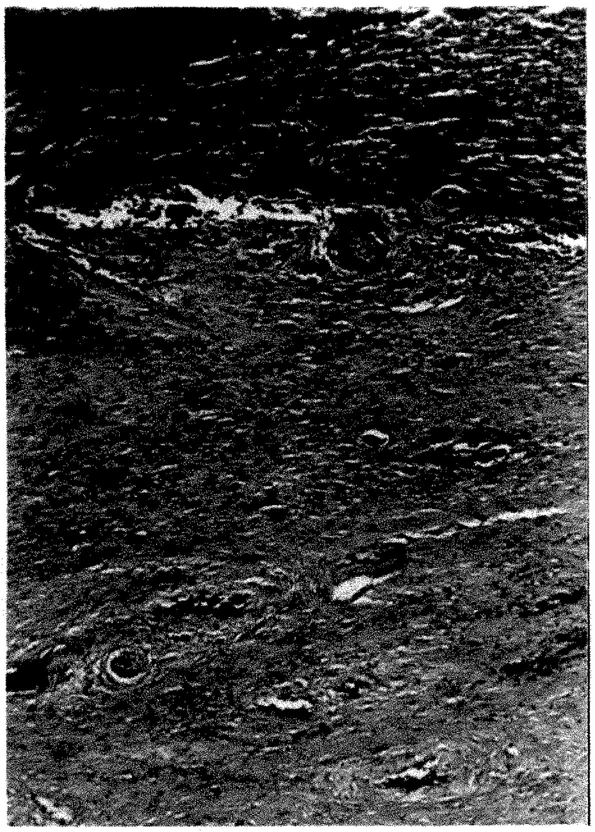

Fig. 3. Numerous microscopic arteriolar thrombi in vaginal wall.

endocardium, myocardium, epicardium of the heart, the pleurae of lungs, kidneys, intestines, liver, and pancreas were noted. Extensive necrosis and hemorrhage of the cervix and vagina were seen (Fig. 2). Numerous microscopic arteriolar thrombi were identified in the heart, lungs, kidneys, gastrointestinal tract, liver, pancreas, wall of the vagina (Fig. 3), and urinary bladder. Local hemorrhage, blood pooling, hemosiderosis, hemophagocytosis, and subendothelial abnormalities were also present.

Two important historic facts were elucidated after the death and autopsy of our patient. First, before her transfer her boyfriend had an influenza-like syndrome with a 2-week history of high fever before seeking medical attention. En route to the hospital, he had a cardiopulmonary arrest and was resuscitated. He died within 24 hours of his admission with a coagulopathy and renal failure with anuria. An autopsy was denied. Second, the patient's mother wrote a letter to the medical records department at the hospital and stated that her daughter recently acknowledged someone had attempted to poison her. A telephone conversation with the patient's mother also revealed a 2-year history of crack cocaine abuse by the patient and the patient's boyfriend.

Comment

The diagnosis of thrombotic thrombocytopenic purpura was confirmed histologically at autopsy. The concomitant findings of arteriolar thrombi, hyaline subendothelial deposits, periarteriolar concentric fibrosis, hemophagocytosis, and hemosiderosis are consistent with the diagnosis of thrombotic thrombocytopenic purpura. Arteriolar thrombi are noted in 75% of thrombotic thrombocytopenic purpura cases.[1] The spleen had numerous periodic acid-Schiff–positive, subendothelial deposits, a common characteristic seen in most cases of thrombotic thrombocytopenic purpura.[2] Hemosiderosis and hemophagocytosis were identified in the spleen, liver, and lungs, a finding in 83% of affected patients. Periarteriolar concentric fibrosis was seen in the spleen and is reported in 58% of patients.[1]

In our case, the history of cocaine abuse, possible poisoning, and the simultaneous illness and subsequent death of her partner suggest a common exposure to an environmental substance as the cause of the syndrome. Reports in the literature that implicate cocaine as an etiologic factor are not noted. However, the cocaine or a contaminant in the crack cocaine could be responsible for triggering the syndrome.

Association of immunoreactive eosinophil major basic protein with placental septa and cysts

Terri L. Wasmoen, PhD,[a] **Carolyn B. Coulam, MD,**[c] **Kurt Benirschke, MD,**[d] **and Gerald J. Gleich, MD**[a, b]
Rochester, Minnesota, and San Diego, California

A protein that is immunochemically indistinguishable from the major basic protein of the eosinophil granule is present at elevated concentrations in the plasma of pregnant women. Major basic protein has been localized to placental trophoblasts known as X cells. Because X cells are located in placental septa and septal cysts, we tested whether the numbers of these structures are correlated with plasma levels of major basic protein. Data analysis revealed strong positive correlations between maternal plasma major basic protein concentrations and the number of placental septa, septal cysts, and subchorial cysts and the presence of subchorial fibrin deposits. No significant correlation was found between plasma major basic protein levels and other variables examined, such as placental weight. Thus major basic protein is a specific marker for septa and cysts, presumably because it is an X-cell product. The study of major basic protein may aid in delineating the function and ontogeny of X cells, as well as their role in fibrin deposition and in septa and cyst formation. (AM J OBSTET GYNECOL 1991;165:416-20.)

Key words: Pregnancy, major basic protein, placental septa, eosinophil, placental cysts

A protein identified immunochemically as the major basic protein of eosinophil granules is present in the plasma of pregnant women at elevated levels ranging from 750 to 8000 ng/ml (nonpregnant, <600 ng/ml).[1] Major basic protein has been localized to placental trophoblastic cells known as X cells.[2] We hypothesized that the X-cell mass would be related to the major basic protein level in the maternal plasma. X cells line septal and subchorial cysts and are found in the cell columns of anchoring villi, in septa, and as cell islands in the basal plate.[3-13] The number of grossly visible septa and septal cysts varies widely from placenta to placenta.

We have quantified the presence of these structures as a measure of X-cell mass to determine whether this mass is related to maternal plasma major basic protein level.

Methods

Placentas were obtained at delivery and stored at 4° C. Surface features examined were cord length, insertion, and vasculature; membrane integrity; presence of subchorial fibrin; and the number of subchorial cysts. The weight and dimensions were recorded after cord and membranes were removed.

Three hundred seventy-nine placentas were examined and the gross morphologic types of each were recorded. In 80 cases plasma was obtained in ethylenediaminetetraacetate from the same women during labor. The plasma was stored at −20° C until subjected to radioimmunoassay for major basic protein as described.[14] Patient histories were reviewed for information regarding weeks of gestation at delivery and gestational complications. The following complications were noted: preeclampsia ($n = 6$, 1.6%), hypertension ($n = 3$, 0.8%), intrauterine growth retardation ($n = 4$, 1.1%), twin gestation ($n = 5$ from three sets of twins, 0.01%), intrauterine fetal death ($n = 1$, 0.3%), and preterm delivery at <37 weeks' gestation ($n = 29$, 7.7%).

Serial sections were cut from the maternal surface to the chorionic membrane to quantitate the total number of septa and septal cysts, the degree of calcification, and the presence of infarcts. Sections were cut at 1 cm intervals by single strokes of a large knife. The cut was exposed by pressing the tissue back with the knife, and the total number of septa seen was recorded. The number of septa seen for each cut was summed to generate an index of the total number of septa per placenta. Septa were recognized as thin, translucent, membranous structures with a grayish hue that extended from the maternal face toward the chorionic membrane. Two septal indices were devised to compensate for the sampling error caused by differences in size of the placentas: (1) total number of septa per number of sections

cut and (2) total number of septa/100 gm of placental weight.

Results

In eight of the 379 placentas, no septa were visible macroscopically. In placentas containing numerous septa, these structures often showed signs of degeneration—presence of perforations, fibrin, calcium deposition, and cysts. Cysts associated with septa ranged from 1 mm to 1 cm in diameter and were filled with a clear mucinous fluid. Macroscopic septal cysts were seen in 92 placentas (24%). Subchorial cysts varied from 5 mm to 6 cm in diameter and were present in 28 placentas (7%). One placenta had three large cysts (Fig. 1) that yielded 30 ml of a straw-colored, mucinous fluid containing major basic protein at 25 μg/ml. The incidence of cysts reported here is in agreement with observations by other authors.[3, 4]

Spearman rank correlation analysis and regression analysis were used to compare the anatomic features of placentas with plasma major basic protein levels in 74 subjects. This group includes those with a plasma sample drawn during labor and does not include those with the gestational complications previously mentioned (six patients). Spearman correlation coefficients are reported in parentheses along with associated

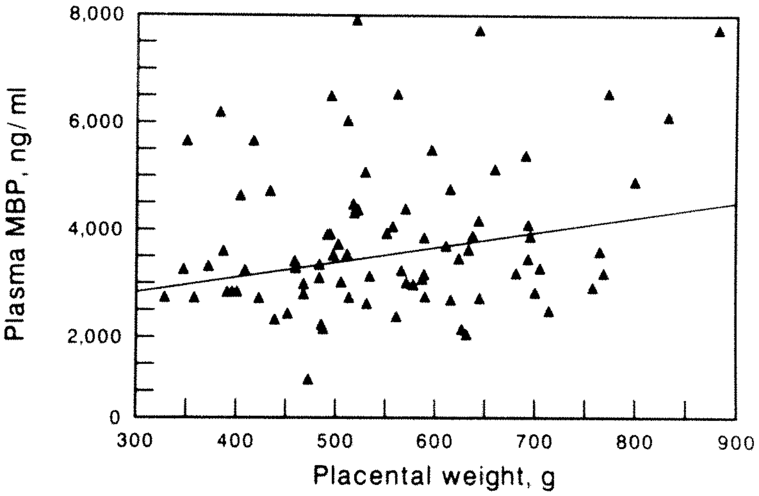

Fig. 3. Relationship between placental weight and plasma major basic protein *(MBP)* (r = 0.2; not significant). This figure includes observations on all 80 patients who had plasma major basic protein measurements, including those six with complications of pregnancy.

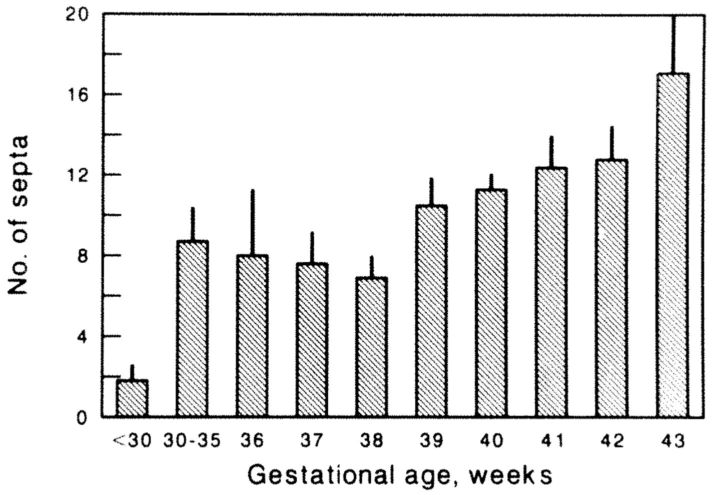

Fig. 4. Relationship between gestational age and placental septa, shown as mean ± SE. For difference between mean number of septa at <30 weeks and at 38 weeks, $p < 0.01$; for difference between mean number of septa at 38 weeks and at 43 weeks, $p < 0.001$.

p values. Plasma major basic protein level was correlated with the total number of septa ($r_s = 0.91, p < 0.0001$), number of septa per section ($r_s = 0.92$, $p < 0.0001$), and number of septa per 100 gm of placental weight ($r_s = 0.96, p < 0.0001$) (Fig. 2). Plasma major basic protein levels also were correlated with the number of septal cysts ($r_s = 0.55$, $p < 0.0001$), subchorial cysts ($r_s = 0.26, p < 0.05$), and presence of subchorial fibrin plaques ($r_s = 0.33$, $p < 0.01$). Unlike the situation reported for many placental proteins,[15] the plasma major basic protein level was not related to the weight of the placenta ($r_s = 0.21, p < 0.05$) (Fig. 3). Major basic protein concentration was not related to any of the other placental variables considered or to fetal gender, fetal weight, maternal age, or maternal parity.

There is an increased number of grossly visible septa in gestationally more mature placentas (Fig. 4).

Comment

Plasma levels of major basic protein in individual pregnant women can vary from 750 to 8000 ng/ml.[1] This study demonstrates that the plasma level of major basic protein is directly correlated with the presence of septa, septal cysts, and subchorial cysts in the placenta. Because these structures contain large numbers of X cells, this suggests that the mass of these trophoblastic cells determines maternal blood levels of major basic protein. This premise is supported by the finding that fluid aspirated from septal and subchorial cysts contains large amounts of major basic protein (up to 100 μg/ml).[2] Furthermore, placental extracts made from septal tissue contain 10 times as much major basic protein per gram of tissue as does whole placenta (unpublished data).

The possibility that major basic protein is a product of X cells has important implications. First, as a specific protein marker for X cells, major basic protein could be useful for defining the poorly understood origin and developmental pathways of these unusual trophoblastic cells.[3, 6, 10-13, 16, 17] For example, the finding that major basic protein is present in placental site giant cells[2] is the first suggestion of a relationship of these cells to X cells. Second, investigation of the biologic properties of pregnancy major basic protein may provide important insights into the poorly understood function of these cells.[3-13, 16, 17] Eosinophil major basic protein, a highly basic protein (isoelectric point > 10),[18] affects clotting,[19] is a potent and unique platelet agonist,[20] and is cytotoxic to parasites and mammalian cells.[18, 21]

We believe that the increase in septa in more mature placentas does not reflect the generation of new septa but rather does reflect a maturation of septa so that they are more clearly visible later in gestation. This finding is supported by ultrasonographic studies of placentas during gestation; echo-free areas representing calcium and fibrin deposits in septa are increasingly apparent from 36 weeks to term, and the appearance of these enlarging anechoic spaces is correlated with mature lecithin/sphingomyelin ratios.[22] Therefore specific changes occur in placental septa that reflect fetal maturity. We believe that this maturation process involves, in addition to fibrin and calcium deposition, cellular degeneration, which is reflected by the presence of septal cysts[12] (cysts were not seen at <35 weeks' gestation). In light of the correlations reported here, major basic protein is implicated as a protein marker for these changes. This is supported by the discovery of a sharp rise in maternal plasma major basic protein levels from 36 weeks to term in most pregnancies.[23]

Recent work has shown that the major basic protein molecule that is extractable from placenta and from septal cyst fluid is essentially indistinguishable from the eosinophil granule major basic protein.[24] Production of a major basic protein cytotoxic molecule by X cells could explain the ability of these cells to invade decidua,[9, 11, 25] the formation of septal and subchorial cysts,[3, 4, 12] and the role of X cells in fibrin deposition.[9, 20, 25] In addition, the study of pregnancy major basic protein may further our understanding of the mechanism of septum formation and the physiologic importance of these structures, which is still in doubt.[3, 4, 16, 17, 23] Finally, because X cells are in intimate contact with maternal decidua, the study of X cell products such as major basic protein may provide insights into the mechanism of fetal allograft maintenance.

We thank Jill M. Wagner for assistance in the data analysis and manuscript preparation.

A case report of massive vulvar edema during tocolysis of preterm labor

Clark Brittain, Maj, MC, USA, Jay W. Carlson, Cpt, MC, USA,
Dan L. Gehlbach, Maj, MC, USA, and Andrew W. Robertson, Maj(P), MC, USA
El Paso, Texas

Bilateral vulvar edema that is not associated with preeclampsia has been reported only rarely during pregnancy or the puerperium. A primiparous patient in premature labor at 34 weeks' gestation with no history of lymphatic or venous obstruction underwent combination tocolysis with intravenous ritodrine and magnesium sulfate. On the fifth day of tocolysis, edema developed in the right labium majus pudendi and gradually spread to the left labia during the ensuing 24 hours. The patient remained afebrile, normotensive, and without signs of localized infection or anasarca. A trial of triple intravenous antibiotics and local skin care proved ineffective. By the ninth hospital day, the edema and discomfort had progressed, thereby precluding vaginal examination without sedation. In spite of progressive cervical dilatation with tocolysis, cesarean delivery was performed. With no further treatment, the vulvar edema gradually resolved during the next week. (AM J OBSTET GYNECOL 1991;165:420-2.)

Key words: Edema, vulvar, bilateral; preeclampsia; tocolysis

A case of bilateral vulvar edema during tocolysis is described.

Case report

A 20-year-old woman, para 1-0-0-1, who did not have prenatal care, presented for evaluation of premature labor 34 weeks after her last menses. She complained of regular contractions but denied vaginal bleeding or rupture of the membranes. Her first pregnancy had resulted in an uncomplicated term vaginal delivery. Physical examination was remarkable for a cervix that had dilated to 3 cm, was 50% effaced, and had a vertex at the −2 station. Ultrasonography was significant for a normal-appearing fetus with an estimated weight of 1980 gm and measurements consistent with 34 weeks' gestation. External fetal heart rate monitoring demonstrated a reassuring fetal heart tracing and contractions every 6 minutes. Laboratory values included a hematocrit of 29%, an O-positive blood type, a nonreactive rapid plasma reagin test, and urine that was leukocyte esterase positive. Two subcutaneous injections of 0.25 mg terbutaline failed to stop the contractions. Therefore intravenous magnesium sulfate was administered for tocolysis. An amniocentesis revealed a lecithin/sphingomyelin ratio of 1.8 : 1 and absence of phosphatidylglycerol. Amniotic fluid and cervical cultures were negative. Because of fetal immaturity, intravenous tocolysis was continued. In addition, intravenous cephapirin sodium was administered for a presumptive diagnosis of cystitis. Magnesium sulfate was

6/1/29549

discontinued because of areflexia, and intravenous ritodrine was started. With the progression of premature labor, low-dose intravenous magnesium sulfate was reinstituted. She continued to have irregular contractions, but there was no further cervical change. On the fourth hospital day the right labia were edematous. There was no evidence of erythema or induration.

During the patient's hospitalization of 8 days, her daily liquid intake exceeded her urinary output by approximately 700 ml per day. She remained normotensive, and skin sensitivity testing failed to reveal evidence of atopy. An empiric trial of nafcillin, gentamycin, and clindamycin was initiated. In spite of additional treatment with ice packs, the edema progressed, involving both labia and the lower extremities by the second hospital day.

On the sixth hospital day, intravenous tocolytics had been discontinued, and oral terbutaline was started. Repeat laboratory values were unremarkable, with the exception of a hematocrit of 22%. Simultaneous values for calcium and albumin were also low, at 8.0 and 2.7 mg/dl, respectively. The patient was anemic and received 2 units of packed red blood cells. By the eighth day of hospitalization, the labial edema had progressed to the point of occluding the vaginal outlet, and cervical examinations could not be performed (Fig. 1). Without evidence of cause, lymphatic occlusion that resulted from an enlarged uterus was thought to be the underlying factor. Because of the resumption of uterine contractions, the inability to assess cervical dilation, and the fear of marked vulvar trauma as a result of vaginal delivery, a primary low-transverse cesarean delivery was performed. A viable 2320 gm female infant was delivered. No edema was noted in the pelvis at the time of operation. The postoperative course was unremarkable, and the vulvar edema spontaneously resolved during the subsequent 4 days.

Comment

Vulvar edema can be an allergic manifestation or can result from a local insult caused by trauma, infection, or vascular or lymphatic obstruction. Vulvar edema has also been associated with systemic disease states that commonly produce pedal edema. In nonpregnant patients these conditions include malnutrition, anemia, congestive heart failure, renal failure, hepatic failure, and malignancies.

Pregnancy complications associated with vulvar edema include preeclampsia and a prolonged second stage of labor. Generalized edema in preeclampsia is usually most pronounced in the dependent areas of the body. Swelling from a prolonged second stage usually occurs after delivery. In addition, the use of the birthing chair has been reported to produce labial edema[1]; both the dependent position and an increased hydrostatic pressure may contribute to the swelling.

In our patient there was no history of or clinical evidence of trauma. Although antibiotics were given empirically, we do not believe that the edema was the result of an infection or was an allergic reaction. The patient did not use a birthing chair, but while she was at bed rest the labia were the most dependent parts of her body.

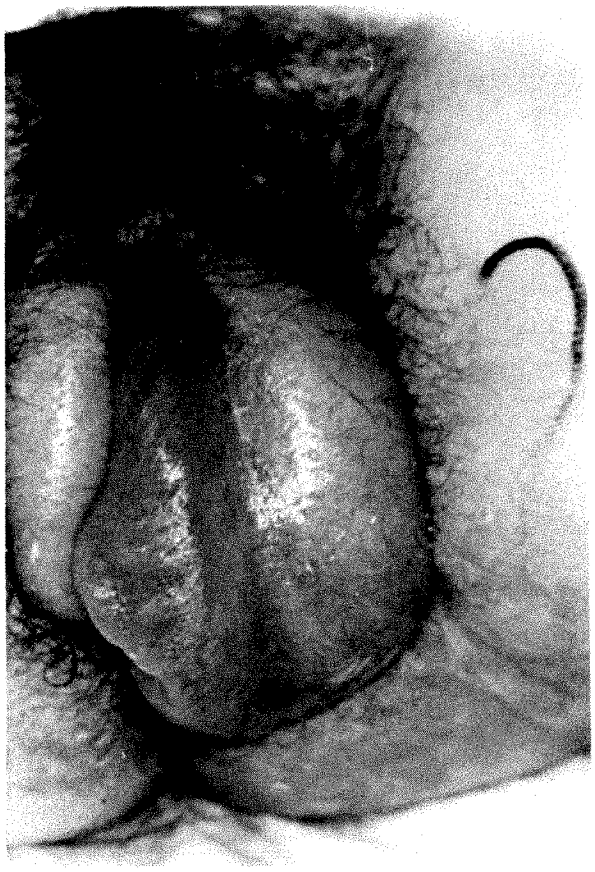

Fig. 1. Edematous labia on hospital day 8.

Fluid retention is a known side effect of intravenous tocolytic therapy, and pulmonary edema is a serious complication of this retention.[2] The fluid retention that accompanies the administration of tocolytics has been attributed to the β-adrenergic receptor agonist effect on the renin-aldosterone system and arginine vasopressin level.[3] Sodium and water retention occurs with subsequent increased hydrostatic pressure and decreased oncotic pressure.[3] The decreased hematocrit without blood loss or hemolysis is consistent with fluid retention and an expanded intravascular blood volume.

There have been several case reports of postoperative fluid shifts that resulted in unilateral or bilateral vulvar edema after the administration of intraperitoneal Hyskon contrast medium. This observation supports the hypothesis of fluid retention from tocolytics as the cause of the vulvar edema in this particular patient.

We postulate that the pathophysiologic characteristics of our case of vulvar edema involved a combination of fluid retention with resultant volume overload, decreased oncotic pressure, and increased hydrostatic pressure that resulted in a net fluid shift from the intravascular to extravascular tissues. This edema was probably most pronounced in the labia because of their dependent nature that was caused by bed rest. We believe that the cause of the fluid retention was a complication of the administration of tocolytic agents.

Uterine activity after preterm premature rupture of the membranes

B.A. Campbell, MD, R.B. Newman, MD, and S.L. Stramm, RN
Charleston, South Carolina

Preterm premature rupture of the membranes complicates few pregnancies but is a major contributor to overall perinatal morbidity and mortality. Although a reduced incidence of preterm premature rupture of fetal membranes has been reported in women who had antepartum uterine activity monitoring, there are few data regarding uterine activity after preterm premature rupture of fetal membranes. Therefore daily uterine activity monitoring was performed in 101 consecutive women with preterm premature rupture of fetal membranes between 26 and 34 weeks' gestation. The mean gestational ages at rupture and delivery were 31.4 ± 2.3 and 33.7 ± 4.5 weeks, respectively. A significant increase in contraction frequency was identified within 24 hours of onset of preterm labor ($p < 0.005$). A contraction frequency of four or more per hour predicted the onset of labor within 24 hours with a sensitivity of 72%, a specificity of 90%, a positive predictive value of 54%, and a negative predictive value of 95%. These results indicate that most women with preterm premature rupture of fetal membranes exhibit a baseline contraction frequency that is similar to that of women with intact membranes and premature labor. An abrupt increase in contraction frequency is a warning of impending labor. (AM J OBSTET GYNECOL 1991;165:422-5.)

Key words: Preterm premature rupture of the membranes, uterine contraction frequency

Although preterm premature rupture of the membranes is an infrequent complication of pregnancy, it contributes significantly to perinatal morbidity and mortality.[1] The most common sequela is respiratory distress syndrome, which occurs in 10% to 40% of preterm infants whose mothers had premature rupture of fetal membranes. Other possible complications include neonatal sepsis, skeletal malformations, pulmonary hypoplasia, abnormal presentations, and cord prolapse. The perinatal mortality associated with preterm premature rupture of fetal membranes has been reported to range as high as 20% to 50%.[2] The cause of preterm premature rupture of fetal membranes is unknown but is likely to be multifactorial. Preterm premature rupture of fetal membranes has been associated with uterine overdistention, cervical incompetence, malpresentation, asymptomatic genital tract infection, and local defects within the membranes.[3-7] Subclinical preterm labor also may have a role in preterm premature rupture of fetal membranes, but no direct supporting evidence exists. This study assesses daily uterine activity monitoring in a large cohort of women with expectant management after preterm premature rupture of fetal membranes. This study was performed to evaluate the possible relationship of preterm premature rupture of fetal membranes and increased uterine activity.

Material and methods

A prospective evaluation of daily uterine activity was performed in 101 consecutive women with preterm

premature rupture of fetal membranes who were between 26 and 34 weeks' gestation. Patients were excluded if there was evidence of active labor, chorioamnionitis, fetal distress, or fetal lung maturity during an initial 24-hour observation period.

During the initial observation, membrane rupture was confirmed by Nitrazine paper testing, ferning of vaginal fluid, and ultrasonographic evaluation of amniotic fluid volume. A visual assessment of cervical dilatation and effacement was performed, and a cervicovaginal culture for group B streptococcus was obtained. Each patient was given antibiotics pending the culture results. Tocolysis was used only during the initial 24 hours. Betamethasone (12 mg intramuscularly, 24 hours apart) was optional in gestations of <30 weeks.

Expectant management included hospitalization with bed rest, no tocolytic therapy for spontaneous labor, twice-daily patient assessment, and twice-weekly fetal assessment. Each patient performed daily uterine activity monitoring from 7 to 9 AM. The patients and clinicians were blinded to the objective uterine activity data. Delivery was allowed for spontaneous labor, chorioamnionitis, fetal pulmonary maturity, or other maternal or fetal indications.

Results are expressed as mean ± SD, and statistical analysis was performed with the Student *t* test and analysis of variance for repeated measures.

Results

Of the women with preterm premature rupture of fetal membranes who were between 26 and 34 weeks' gestation and who were evaluated at our institution between July 1987 and October 1988, 65% ($n = 101$) were candidates for expectant management. The mean patient age was 24.2 ± 5.7 years, and the mean gravidity and parity were 2.8 ± 1.8 and 1.3 ± 1.6, respectively. The mean gestational age at premature rupture of fetal membranes was 31.4 ± 2.9 weeks, and the mean gestational age at delivery was 33.7 ± 4.5 weeks. The latent period for women qualifying for expectant management was 5.3 ± 2.7 days. Indications for delivery included spontaneous labor ($n = 79$), chorioamnionitis ($n = 8$),and maternal-fetal indications ($n = 14$).

The hourly contraction frequency for each day preceding the onset of labor in those women with spontaneous labor after preterm premature rupture of fetal membranes is presented in Fig. 1. There is no significant difference between this uterine activity pattern and that previously reported (Fig. 2) for a group of women with spontaneous preterm labor and intact membranes.[7]

Comment

Despite a significant contribution to perinatal morbidity and mortality, the cause of preterm premature rupture of the membranes remains unknown. Many factors are thought to play a role in preterm premature rupture of fetal membranes, including genital tract infections, uterine overdistention, abnormalities of the internal cervical os, and excessive subclinical uterine activity. This study attempts to address the relationship between uterine activity and preterm premature rupture of fetal membranes.

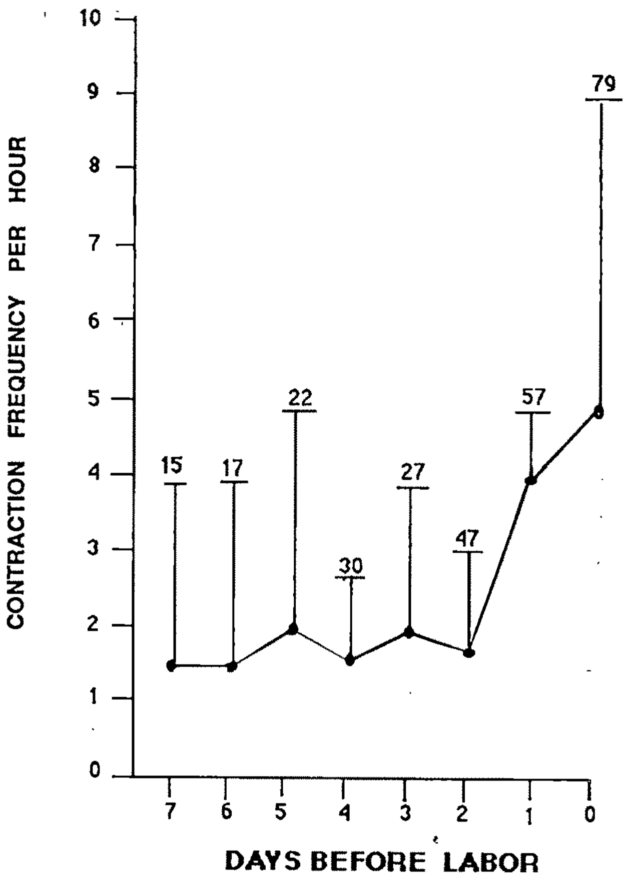

Fig. 1. Average number of contractions each day during expectant management in patients with preterm premature rupture of fetal membranes.

The major finding of this investigation is that most women with expectant management of preterm premature rupture of fetal membranes seem to have a pattern of uterine activity that is similar to that of women who later have preterm labor with intact membranes. Excessive rates of uterine contractility typical of impending preterm labor were not seen in the women immediately after preterm premature rupture of fetal membranes. It seems likely that excessive subclinical uterine activity is not a major factor in most cases of preterm premature rupture of fetal membranes. An obvious question concerns whether the uterine activity after preterm premature rupture of fetal membranes reflects uterine activity that may have preceded rupture of the membranes. It seems unlikely that excessive uterine activity before preterm premature

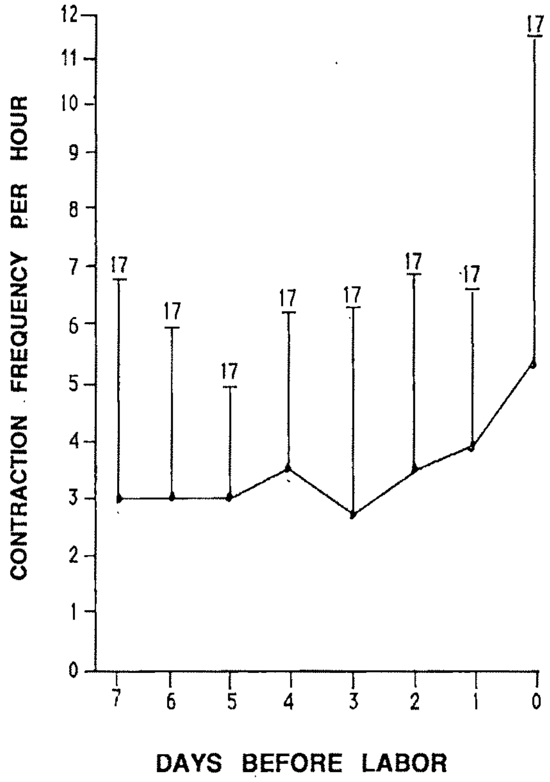

Fig. 2. Average number of contractions each day in patients with intact membranes and spontaneous labor. (From Katz M, Newman RB, Gill PJ. Assessment of uterine activity in ambulatory patients at high risk of preterm labor and delivery. Am J Obstet Gynecol 1986;154:44.)

rupture of fetal membranes would disappear after rupture. It is important to note that 35% of the women with preterm premature rupture of fetal membranes betweeen 26 and 34 weeks' gestation in our institution were not candidates for expectant management. A variety of reasons, including active labor, may explain why these women were not candidates for expectant management. Among these women, excessive uterine activity leading to preterm premature rupture of fetal membranes and then evolving to active labor easily could have occurred.

To optimally evaluate the relationship between uterine activity and preterm premature rupture of fetal membranes, it would be necessary to monitor uterine contraction frequency before rupture of the membranes. Clinical trials of home uterine activity monitoring have reported low rates of premature rupture of fetal membranes, which suggests that interventions to reduce excessive uterine activity may help prevent this complication.[8, 9] However, because of the difficulty in identifying women at risk for preterm premature rupture of fetal membranes and the ethical concerns raised by ignoring excessive prelabor uterine activity in women at such risk, it is unlikely that a definitive study of uterine activity preceding preterm premature rupture of fetal membranes will be possible.

During expectant management, the development of an excessive uterine contraction frequency (four or more contractions per hour) is a strong indicator of impending preterm labor. The onset of spontaneous preterm labor was preceded by an excessive contraction frequency in >70% of the patients studied. Martin et al.[10] previously reported very similar findings in a small group of patients with premature rupture of fetal membranes that was managed conservatively. Among women with preterm premature rupture of fetal membranes, the positive predictive value and sensitivity of a baseline contraction frequency of four or more contractions per hour were 54% and 72%, respectively. A contraction frequency of fewer than four contractions per hour was reassuring that labor would not ensue within the next 24 hours (negative predictive value, 95%, specificity, 90%). This predictive information regarding impending preterm labor could be helpful in the management of women with abnormal presentations who are at risk for cord prolapse or birth trauma. Some investigators have suggested the use of antibiotics and tocolysis to prolong pregnancy complicated by preterm premature rupture of fetal membranes.[11] The early identification of impending preterm labor may be of value in determining the role of ascending genital tract infection in premature rupture of fetal membranes and in maximizing the therapeutic potential of tocolytic agents. This information would be of great use if other management plans were used that placed a premium on the early diagnosis of preterm labor in women with preterm premature rupture of fetal membranes.

After preterm premature rupture of fetal membranes, the crescendo of uterine activity leading to the diagnosis of spontaneous labor is very similar to the pattern demonstrated by women with intact membranes. It appears that the status of the membranes does not affect the evolution of uterine activity necessary to initiate preterm labor. Although rupture of the membranes does not appear to be associated with excessive uterine contractility in most cases, the short latent period indicates that preterm premature rupture of fetal membranes is a powerful facilitator of preterm labor. We believe that the ultimate onset of labor in this patient population is often associated with an ascending decidual or chorioamniotic infection.

Obstetric complications in a patient with Bernard-Soulier syndrome

Thomas C. Peng, MD, Thomas S. Kickler, MD, William R. Bell, MD, and Emily Haller, MD
Baltimore, Maryland

We describe the obstetric complications and management of a patient with Bernard-Soulier syndrome. Severe bleeding at the time of delivery and delayed postpartum hemorrhage were prominent features of her pregnancies. Further complicating this woman's pregnancies was the development of antibodies to platelet glycoprotein IB/IX, leading to neonatal alloimmune thrombocytopenia. (AM J OBSTET GYNECOL 1991;165:425-6.)

Key words: Neonatal alloimmune thrombocytopenia, Bernard-Soulier syndrome

Individuals may lack the membrane glycoprotein IB/IX, leading to Bernard-Soulier syndrome, which is characterized by platelet dysfunction. Life-threatening bleeding may occur spontaneously or after invasive procedures. Women lacking these glycoproteins are also at risk of being immunized by fetal platelets during pregnancy. We report on a mother with Bernard-Soulier syndrome who was immunized to platelet glycoprotein IB/IX, leading to neonatal thrombocytopenia.

Case report

A 35-year-old woman had Bernard-Soulier syndrome. Her first pregnancy, which occurred in 1972, was uneventful. Postpartum hemorrhage necessitated 11 units of blood. In 1986 her second pregnancy ended with in utero fetal death at 38 weeks' gestation, concomitant with severe third-trimester gastrointestinal bleeding. Vaginal bleeding necessitating 8 units of blood occurred 2 weeks after delivery. Treatment with aminocaproic acid significantly reduced the vaginal bleeding. In 1987 a third pregnancy resulted in an infant with a platelet count of 51,000/mm^3. In 1988 she was seen for her fourth pregnancy. At the onset of labor she received 50 gm γ-globulin intravenously. Vaginal delivery of a nonthrombocytopenic infant occurred 28 hours later. ε-Aminocaproic acid was initiated post partum, 5 gm intravenously, then 2 gm every 6 hours for 24 hours. Post partum she experienced moderate vaginal bleeding that necessitated four units of blood. After the addition of methergine, the bleeding decreased. The ε-aminocaproic acid was continued for 4 weeks.

Platelet antibody studies. After the third pregnancy the patient's serum was tested with an antiglobulin test that had a radioactive label against platelets from 20

6/1/29135

donors; it reacted strongly with all platelets. In the fourth pregnancy a sample collected during the first trimester showed similar serologic results. The serum was also tested in a solid-phase assay where antibodies to specific glycoproteins can be identified.[1] The antibody specificity recognized the platelet glycoprotein IB/IX.

Comment

The management of this case was complicated by abnormal platelets and alloimmunization to the fetus' platelets. We were reluctant to assess the fetal platelet count prenatally, because percutaneous umbilical blood sampling could lead to uncontrollable maternal bleeding. If bleeding should occur, we could not satisfactorily transfuse the patient with platelets because of alloimmunization to platelets. Second, for similar reasons cesarean section was not considered as an option for delivery. Third, in the event that fetal thrombocytopenia was diagnosed, suitable platelet transfusions were not available for in utero transfusion.

In our patient with Bernard-Soulier syndrome, through hundreds of platelet transfusions and multiple pregnancies, she became sensitized to platelet antigens. This was first suspected when she failed to receive any therapeutic benefit from platelet HLA-matched platelet transfusions. Subsequently we were able to document an antibody to platelet glycoprotein IB/IX. The unique obstetric problem of this patient related not only to the risk of maternal bleeding because of the qualitative platelet defect but also to the infant's risk of thrombocytopenia because of the passive transfer of platelet antibodies. Since the fetus of a mother with Bernard-Soulier syndrome would be heterozygous for the disorder, the fetal platelets carry antigenic determinants to which the mother's antibody can bind. We thought that this was the basis of the thrombocytopenia in the third pregnancy and that subsequent pregnancies would be complicated by this problem. In the fourth pregnancy these antibodies were again demonstrable.

Because of these considerations, we elected to treat the patient with intravenous γ-globulin in an attempt to reduce the risk of thrombocytopenia. In our patient management with intravenous γ-globulin appeared to be successful in preventing neonatal alloimmune thrombocytopenia. Unlike the pregnancy with her third child, the last pregnancy, in which intravenous γ-globulin was given, was not associated with a thrombocytopenic baby. Since we were unable to obtain pre–intravenous γ-globulin treatment fetal platelet counts, we cannot prove the efficacy of the intravenous γ-globulin.

Obstetric experience in women with Bernard-Soulier syndrome is not commonly reported.[2] Our experience suggests that women with Bernard-Soulier disease may be at risk for severe hemorrhage at the time of delivery. Because these patients may be alloimmunized to platelet glycoprotein IB/IX, platelet transfusions may be ineffective. Delayed bleeding up to 2 to 3 weeks post partum is not uncommon. Patients should be cautioned about this possibility. One should be cautious about performing any type of invasive procedure since uncontrollable hemorrhage may result. Our report also emphasizes that the obstetrician must consider the risk of neonatal alloimmune thrombocytopenia in the fetus and manage this problem accordingly.

Acute cutaneous vasculitis associated with prolonged intravenous ritodrine hydrochloride therapy

Stacie Bosnyak, MD,[a] Joseph M. Baron, MD,[b] and James Schreiber, MD[a]
Chicago, Illinois

A patient with twin gestation was hospitalized because of preterm labor and treated with intravenous ritodrine hydrochloride (Yutopar, Astra Pharmaceutical Products, Westborough, Mass.). After >4 weeks of therapy, the patient had a petechial rash and prolonged bleeding time, which were diagnosed and confirmed by skin biopsy at cesarean section as vasculitis. This is the first documented case of vasculitis associated with ritodrine use. (AM J OBSTET GYNECOL 1991;165:427-8.)

Key words: Preterm labor, cutaneous vasculitis, ritodrine

Preterm delivery, before 37 weeks' gestation, occurs in 5% to 10% of all pregnancies in developed countries and accounts for 60% to 90% of perinatal mortality in infants without anomalies. β-Sympathomimetic amines are a well-accepted and frequently used treatment for preterm contractions since Food and Drug Administration approval in 1980. Ritodrine hydrochloride (Yutopar, Astra Pharmaceutical Products, Westborough, Mass.) is a β_2-adrenergic agonist that relaxes uterine muscle by a hypothesized cyclic adenosine 5′-monophosphate—mediated mechanism. Common side effects include tachycardia, nausea, hypokalemia, and flushing, which necessitate discontinuation of therapy in 3% to 10% of patients. More serious side effects include hypotension, cardiac arrhythmias, myocardial ischemia, and pulmonary edema, which have been observed in 1% to 5% of cases. In our institution we encountered a case of vasculitis, previously unreported, after prolonged β-sympathomimetic tocolysis.

Case report

A 30-year-old woman, gravida 1, para 0, was diagnosed by ultrasonography to have twins at 10 weeks' gestation. She had no significant medical or surgical history, including no history of arthritis, autoimmune disease, petechial rash, or thrombocytopenia. Platelet counts of 280,000/mm³ and 209.000/mm³ were measured at 18 and 14 months, respectively, before delivery. At 29 weeks' gestation, the patient noted mild contractions, and she was placed on bed rest and started on a regimen of oral ritodrine hydrochloride, 10 mg every 6 hours. One week later she felt increasing contractions and was admitted to the hospital in preterm labor. At that time she had a sonogram consistent with her dates, a cervical examination showing 2 cm dilatation and 50% effacement, and monitored contractions occurring every 4 to 6 minutes. Admission laboratory studies included white blood cell count, 6400/mm³; hematocrit, 35.6%; platelet count, 149,000/mm³ (150,000 to 450,000/mm³ is normal); fibrinogen, 380 mg/dl (200 to 400 mg/dl is normal); and antithrombin III, 91% (84% to 116% is normal).

She was begun on a regimen of intravenous ritodrine hydrochloride at 100 μg/min and contractions abated. Any attempt to change to a regimen of oral ritodrine or to decrease the amount of intravenous ritodrine resulted in return of contractions. On this medication regimen fibrinogen, hematocrit, and serum potassium level remained stable. She was continued on the regimen of intravenous ritodrine at 100 μg/min for 5 weeks. At 34 weeks' gestation (5 weeks after admission) a nonpalpable, nonpruritic petechial rash appeared initially on the forearms and later extended to all extremities. She had no mucosal bleeding, hematuria, hematochezia, or palpable hepatosplenomegaly. Hematologic studies included white blood cell count, 5000/mm³; hematocrit, 34%; platelets, 125,000/mm³; prothrombin time, 11.1 seconds (normal); partial thromboplastin time, 25.2 seconds (normal); fibrin degradation products, >10 <20 μg/ml; and template bleeding time, 13 minutes (normal, 2 to 9 minutes). Factors V (100%), VII (120%), and VIII (100%) and plasminogen (96%) were normal. Antithrombin III was decreased at 68%. Platelet aggregation was normal with the agonists adenosine 5′-diphosphate, collagen, ristocetin, epinephrine, and arachidonic acid. Other normal or negative studies included creatinine clearance (89 ml/min), antinuclear antibodies, rheumatoid factor, serum complement (C′3 and C′4), cryoglobulins, electrolytes, liver function tests, and fibrinogen (393 mg/dl). The findings of prolonged bleeding time and petechial rash, combined with normal platelet function and only slight thrombocytopenia, suggested vasculitis.

Her only medications, other than ritodrine, were prenatal vitamins and mineral supplements.

Ritodrine was discontinued and 100 mg hydrocortisone was infused intravenously. Four hours later the bleeding time was normal (6.5 minutes), and the patient underwent an uncomplicated, low-segment, transverse cesarean section while she was under general anesthesia, with delivery of a 1700 gm male infant, with Apgar scores of 9 and 9 at 1 and 5 minutes, and a 2100 gm male infant, with Apgar scores of 3 and 9 at 1 and 5 minutes, respectively. The infants had normal platelet counts and no bleeding problems. Pathologic examination of a biopsy specimen of the abdominal skin at the incision site revealed a leukocytoclastic vasculitis, diagnosed by the presence of neutrophils and fibrin in the walls of small arterioles.

The patient received intravenous hydrocortisone (100 mg every 6 hours) for the first postpartum day. The rash improved with the corticosteroids, which were tapered and discontinued by the third day. She was discharged home on postoperative day 5 with minimal residual rash. Follow-up platelet count on postpartum day 7 was $224,000/mm^3$.

Comment

Ritodrine hydrochloride is a frequently used tocolytic for the commonly occurring complication of pregnancy, preterm labor. Our patient was seen with uncomplicated mild thrombocytopenia that was persistent throughout successful prolonged intravenous ritodrine therapy (5 weeks). A biopsy-proved acute cutaneous vasculitis developed with prolonged template bleeding time. Platelet count would not have been expected to result in a prolonged bleeding time, and in vitro platelet function tests were normal. She was otherwise healthy and not receiving any other medication, other than the ritodrine, that might be incriminated as a cause of either thrombocytopenia or vasculitis. We conclude that vasculitis was likely associated with ritodrine infusion. However, mild thrombocytopenia is less easily related to the drug, in view of the frequency of mild asymptomatic thrombocytopenia of unclear cause in late pregnancy.[1]

Only rarely have other hematologic and cutaneous complications been related to ritodrine. These include erythema multiforme[2] and neutropenia after 26 days of ritodrine.[3] We have been able to find no other reported cases of vasculitis or thrombocytopenia associated with ritodrine use, and the manufacturer also is unaware of any. Discontinuation of ritodrine and administration of corticosteroids were followed within 4 hours by normalization of the bleeding time, which permitted uncomplicated twin delivery by cesarean section. The rash subsided over several days, and the platelet count returned to antepartum levels by the seventh postpartum day. This report should alert the clinician to the possibility of unusual hematologic and cutaneous complications associated with prolonged parenteral ritodrine therapy.

Bound volumes available to subscribers

Bound volumes of the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY are available to subscribers (only) for the 1991 issues from the Publisher, at a cost of $61.00 for domestic, $88.27 for Canada, and $84.00 for international for Vol. 164 (January-June) and Vol. 165 (July-December). Shipping charges are included. Each bound volume contains a subject and author index and all advertising is removed. Copies are shipped within 60 days after publication of the last issue in the volume. The binding is durable buckram with the JOURNAL name, volume number, and year stamped in gold on the spine. *Payment must accompany all orders.* Contact Mosby–Year Book, Inc., Subscription Services, 11830 Westline Industrial Drive, St. Louis, MO 63146-3318, USA; phone (800) 325-4177, ext. 4351.

Subscriptions must be in force to qualify. Bound volumes are not available in place of a regular JOURNAL subscription.

The three most common occupational exposures reported by pregnant women: An update

Yedidia Bentur, MD, and Gideon Koren, MD
Toronto, Ontario, Canada

Many uncertainties exist in regard to counseling women with occupational exposures during pregnancy. This is due to limited knowledge of the reproductive toxicologic effects of industrial agents, lack of safety standards aimed at protecting the fetus, and limitations in assessing the extent of exposure. The approach to this subject taken by the Motherisk Program and a review of the three most common occupational exposures are presented. Epidemiologic studies and measurements of radiation do not suggest a reproductive hazard for video display terminals. Exposure to organic solvents is hard to quantitate, and information is sparse and sometimes contradictory, and therapeutic decisions are difficult to reach. To date there is no convincing evidence that working with organic solvents within safety regulations would harm a fetus, in contradistinction to detrimental fetal effects of solvent abuse. The reproductive risks of lead are well documented, fetal exposure can be assessed, and effective treatment exists, but its effects on the pregnancy have not been fully established. However, new evidence suggests that maternal levels that are much lower than the accepted adult limits may be damaging to the fetus. (Am J Obstet Gynecol 1991;165:429-37.)

Key words: Video display terminals, organic solvents, lead, pregnancy, fetus

It is clear from animal experiments and human epidemiologic studies that industrial chemicals have the potential of being reproductive toxins. However, the knowledge of reproductive toxicology of industrial chemicals in humans is sparse or absent. Before therapeutic agents are marketed, their teratogenic potential has to be tested in animals; no such data have to be presented for chemicals. Other factors may also be different between medical and occupational exposures. In the workplace the exposure is usually to more than one chemical, and in some cases one has to deal with possible unknown by-products. The amounts of the chemicals absorbed are often unclear, and the circumstances of exposure may vary between different plants or even within the same operation. Every chemical in the workplace has safety exposure limits aiming at protecting the worker. However, these standards were not meant to protect the fetus. Hence, even if one can obtain exposure levels, one is never sure whether safe levels to the mother are also safe for her unborn baby; lead is a good example of such a discrepancy.[1, 2]

To approach the occupationally exposed woman the following steps may be suggested:

1. Identify the chemicals in question, by their safety sheets if possible.
2. Identify symptoms and signs reported to be associated with the chemicals.
3. Rule out underlying conditions that may cause a similar clinical picture (e.g., morning sickness).
4. Obtain a detailed description of the work performed by the woman, length of exposure, means of protection (ventilation system, respirator, mask, gown, gloves, hood, etc.).
5. Are there symptoms and signs in fellow workers?
6. What is the pregnancy outcome in other workers?
7. Obtain the most recent levels of the chemicals in question measured in that particular area.
8. Try to understand the attitude of the woman and her supervisors toward her particular work and toward possible change of job; will it affect her income or promotion?
9. Before reporting to the woman on available information, evaluate the data critically to allow the patient accurate information.
10. Advise the woman on possible safety measurements to reduce exposure (mask, gloves, ventilation, etc.).

All these steps should be completed by obtaining a good medical history, estimating the gestational age, evaluating genetic diseases, and assessing the presence of other risk factors (alcohol use, cigarette smoking, concomitant drugs, chronic diseases, etc.).

The Motherisk program in Toronto is an antenatal counseling service for health professionals, women and their families, dealing with drug, chemical, radiation, and infection exposure in pregnancy and lactation. Presently, between 40 and 50 telephone calls are dealt with daily. Women are referred to our clinic if they have been exposed to known or suspected teratogens, long-term drug therapy, new drugs on which there is sparse or no information, drugs of abuse, and occupational exposures. After the expected date of confinement, follow-up of pregnancy outcome is performed, and all data are computerized for clinical and research use.

In the Motherisk Program we are frequently called about exposure to chemicals and radiation during pregnancy. During 1988 we received 5040 telephone calls; 167 (3.3%) of them were due to occupational exposures to video display terminals (Table I). This exposure is the most frequent one that we encounter in the workplace. Organic solvents were the concern of up to 150 of the telephone calls, most of them due to the use of oil-based paints, some of them at home. In 56 the exposure to organic solvents occurred in the workplace, and 24 of these were followed up in our clinic (Table II). We also advised 29 patients who were exposed to lead (most of them in the form of paints); six were occupationally exposed, and three were seen in the clinic.

The purpose of this article is to review the state of our knowledge on the reproductive hazards of these three exposures, to give the clinician up-to-date information with which to advise women.

Video display terminals

Over the last years the microprocessor has brought video display terminals into offices and homes. and a massive increase in their use has been observed. It was estimated that in the United States 7 million people were occupationally exposed to video display terminals in 1980.[3] The expansion of their use has prompted concerns about their reproductive effects.

About 10 years ago clusters of cases of adverse pregnancy outcome in workers exposed to video display terminals were reported, some of them in the lay media.[4-7] The most widely publicized cluster was reported by the *Toronto Star*, where over a year's time four of seven pregnant women working with video display terminals gave birth to children with birth defects.[6] These defects were different in each affected child and included clubfoot, underdeveloped eye, cleft palate, and a congenital heart defect. Additional clusters involved spontaneous abortions, Down syndrome, neural tube defects, prematurity, and neonatal respiratory disease. Evidently, none of these reports represents a distinct or reproducible syndrome. Miscarriages, for instance, are not evenly spread in time and space and some clustering is to be expected. Hence the occurrence of clusters does not prove causality but rather may increase the level of suspicion. A partial answer may come from looking at the physical properties of video display terminals and from epidemiologic studies.

The ionizing radiation generated by the video display terminal consists of x-rays, the adverse reproductive effects of which are well known. However, x-rays emitted by the cathode ray tube in the video display terminal are entirely absorbed by the glass screen.[8] Several studies could not detect measurable ionizing radiation from video display terminals (0.01 to 0.05 mR/hr.[8-12] This was also the case in the reported clusters where the video display terminals involved were tested. Current regulations require that x-ray emissions from any cathode ray tube, including video display terminal, will be <0.5 mR/hr.[4] Even at this maximum level the amount of uterine radiation for a woman sitting 50 cm from the screen, working 30 hours a week, is 6 mrem during the first trimester.[13] This is one fourth of the natural background radiation, which is by itself very minimal.

The nonionizing radiation transmits energy to tissues mainly as heat and it includes the following:

1. Ultraviolet and visible light (emitted by the phosphor target of the screen) are two to five orders of magnitude less than that of the environment.[9, 11] The amount of heat they produce is very small ($1.72 \cdot 10^{-6}$ cal) and their wavelength is not in the dangerous range (>336 nm; harmful, <300 nm).[11]
2. Infrared radiation has never been detected from the video display terminals tested.[9, 11]
3. Microwaves and radiofrequency radiation emitted are in the same frequency range as that given off by most home electrical appliances.[9] This amount of radiation is two orders of magnitude less than the background.[11] Some video display terminals are equipped with a flyback transformer, which is responsible for moving the arm of the cathode ray tube back and forth. People coming near the back casing of such a unit may be exposed to a lower-

frequency electromagnetic radiation, which is thought to be more dangerous.[6] This problem was solved with modified casing.

In short, ionizing radiation is practically unmeasurable and the amount of nonionizing radiation is very small, several orders of magnitude less than the background radiation, and cannot be considered as harmful to the fetus.

Epidemiologic studies might be fraught with pitfalls. Confounding factors include reproductive history (miscarriage, anomalies), maternal age, maternal smoking, selection bias, and recall or response bias between the exposed and the control groups. So far, no epidemiologic study has demonstrated a higher risk of miscarriages and birth defects.[14-18] Some studies that initially suggested some association were found by the authors themselves to be subjected to selection bias and recall bias,[14, 18] and in another one response bias seemed to be a possible explanation for such an association.[19]

On the basis of current data and because a very large number of women are exposed occupationally to video display terminals without emergence of a peak of any specific pattern, it seems likely that the clusters reported were encountered by chance.[6]

Consequently, in the Motherisk Program we do not feel that there is a need for a concern or a change in working conditions. We may suggest, in very selected cases, as is done in other countries (Sweden, England), that women may request to leave work with video display terminals on the grounds of reducing anxiety only.[20, 21]

Organic solvents

In our clinic we often counsel women who are exposed occupationally to numerous chemicals, most of which are organic solvents. A proper consultation in such cases is extremely difficult, because it is hard to estimate the predominant chemicals and their byproducts. Even if one identifies the more toxic ones, it is still hard to assess the circumstances of exposure. For many chemicals one can measure neither airborne nor blood levels. Smelling the odor of organic solvents is not indicative of a significant exposure, because the olfactory nerve can detect levels as low as several parts per million, which are not necessarily associated with toxicity. Finally, reproductive information on most solvents is sparse, either limited to animal studies or nonexistent.

Organic solvents are a structurally diverse group of low-molecular-weight chemicals that are liquids and are able to dissolve other organic substances.[22] They are ubiquitous in our industrialized society, both at work and at home, and may be encountered as individual agents or in complex mixtures such as gasoline. Chemicals in the solvent class include aliphatic hydrocarbons (such as mineral spirits, varnish, and kerosene), aromatic hydrocarbons (benzene, toluene, xylene), halogenated hydrocarbons (carbon tetrachloride, trichloroethylene, methylcellulose), aliphatic alcohols (acetone), glycols (ethylene glycol), and glycol ethers (methoxyethanol).[23, 24] Fuels are mixtures of various hydrocarbons.

Table II. Distribution of occupational exposures with clinic follow-up in 1988

	No.	*Total clinic visits* (%)*	*Occupational exposures seen in clinic† (%)*
Organic solvents‡	24	6.3	66.6
Video display terminals§	5	1.3	13.8
Lead‖	3	0.8	8.3
Polychlorinated biphenyl	2	0.5	5.5
Miscellaneous¶	5	1.3	13.8

*A total of 380 patients were seen in the clinic.

†Thirty-six patients with occupational exposures were monitored in the clinic.

‡Two patients were exposed to organic solvents and lead.

§Four patients came to the clinic because of drug exposure.

‖Two patients were exposed to lead and organic solvents.

¶Each patient was exposed to multiple chemicals, no organic solvents.

The mechanisms by which many solvents exert their toxicity are unclear and may vary from one solvent to another. Halogenated hydrocarbons such as carbon tetrachloride may generate free radicals.[22] Simple aromatic compounds such as benzene may disrupt polyribosomes,[25] whereas some solvents are thought to affect lipid membranes and penetrate tissues such as the brain.

Incidental exposures may include vapors from gasoline, lighter fluid, spot removers, aerosol sprays, and paints.[26] These are short-duration, low-level exposures and may go undetected. More serious exposures occur mainly in industrial or laboratory setting during manufacturing and processing operations. This includes paint removers, thinners, floor and tile cleaners, glues, and laboratory reagents. Gasoline or glue sniffing, although not occurring in the occupational setting, are other sources of exposure to organic solvents during pregnancy.

Workers with short-term exposure to organic solvents experience fatigue, concentration disorder, drunken feeling, dizziness, pneumonitis, and vomiting.[21] Long-term exposure may irreversibly affect the central nervous system and liver and may cause blood disorders (e.g., exposure to benzene).

Although the toxic effects of organic solvents are relatively known in the adult, there is a paucity of information on the impact of in utero exposure.

In 1988 our patient population included 150 (2.9%) cases of telephone counseling and 24 clinic consultations dealing with organic solvents (Tables I and II). Most of the occupationally exposed women were seen in the clinic, and most of them were involved in manufacturing, processing, and application of paints and glues. Others were machinists, laboratory technicians, and dry cleaners.

It is beyond the scope of this article to review all the organic solvents, so we chose toluene as an illustrative example of exposure. This agent is used in a variety of mixtures and products. Also important, it is a common substance of abuse. Toluene is an aromatic hydrocarbon used as a solvent for paints, thinners, coatings, and glues.[23] It is a popular replacement for the more chronically toxic benzene solvents. Most exposures involve inhalation; however, absorption is almost complete after oral administration.[23] Toluene inhalation by pregnant rats induced decreased fetal weight and skeletal growth retardation.[27] No malformations were demonstrated in rats or mice after inhalation,[27, 28] but oral administration to mice induced cleft palate.[29] A study from 1977 compared pregnancy outcomes among 168 women occupationally exposed to varnishes containing toluene (55 ppm) with those of 201 control women.[30] While there were twice as many low-birth-weight infants in the toluene-exposed group, the two groups did not differ with regard to fertility, course of pregnancy, perinatal mortality, or adverse effects in the newborn. Unfortunately, congenital defects were not evaluated. Occupational exposure to aromatic solvents, mainly to toluene, was suggested to be associated with various birth defects, predominantly renal-urinary or gastrointestinal.[31] Abuse of large quantities of pure toluene by inhalation throughout pregnancy was reported in three patients to result in microcephaly, central nervous system dysfunction, and minor craniofacial and variable growth deficiencies.[32] These features resembled the pattern of malformations described with alcohol or certain anticonvulsant medication exposure and were defined as "fetal solvent syndrome."

Many organic solvents are teratogenic and embryotoxic in laboratory animals, depending on specific solvent, route of administration, and animal species.[22, 26] Malformations described include hydrocephalus, exencephaly, skeletal defects, cardiovascular abnormalities, and blood changes. Other abnormalities include poor fetal development and neurodevelopmental deficits. In some of the studies exposure levels were high enough to induce maternal toxicity.

Because of the complexity and diversity of organic solvents and because exposure usually involves more than one agent and different circumstances, adequate human epidemiologic studies are difficult to conduct and interpret. In addition, studies are subjected to recall and response bias and are not always controlled for other risk factors (age, smoking, etc.). Isolated case reports suggesting solvent-related embryopathy to occur in humans have appeared for many years. In one report five of nine women who gave birth to infants with caudal regression syndrome were exposed to solvents, including xylene, trichloroethylene, methyl chloride, acetone, and gasoline.[33] These agents do not belong to the same subgroup of organic solvents, and it is impossible to identify the potential culprit. Several epidemiologic studies suggested association between adverse pregnancy outcome and exposure to organic solvents. Although these solvents may have common chemical features, there is no indication that they were teratogenic as a group or on an individual basis. These studies reported esophageal stenosis or atresia in babies of female laboratory workers,[34] omphalocele or gastroschisis in offspring of mothers in the printing industry,[35] an association between increased risk of malformations and laboratory work in the pharmaceutical and paper industries.[36, 37] Case-control studies of central nervous system defects in Finland showed an association with organic solvents.[38, 39] However, another study from Finland could not prove this association.[40] A cumulative case-referent study covering 3.5 years suggested an association of organic solvent with cleft palate.[41] The prevalence of exposure to organic solvents at work during the first trimester was 10.4% among 569 mothers of children with cardiovascular malformation compared with 7.8% in the control group.[42] This retrospective study found an adjusted relative odds ratio of 1.3 for cardiovascular malformations and 1.5 for ventricular septal defects, both probably insignificant. A recent study from California could not demonstrate any difference in neurobehavioral development and growth between children exposed in utero to organic solvents and a group of matched, unexposed children.[43] A recent study published by the same group suggested an association between exposure to organic solvents and preeclampsia.[44] No correlation was found between laboratory work and sister chromatid exchanges and micronuclei in 59 Canadian laboratory workers.[45] There was, however, an association between such exchange and recent or past smoking.

A higher risk for spontaneous abortions was reported in hospital laboratory and factory workers.[46, 47] This was also the case in 262 factory workers in Denmark.[48] However, when controlled for gravidity there was no longer a statistically significant increased risk. No increased risk for miscarriage was found in university laboratory workers exposed to organic solvents.[49] Conversely, shift work in these workers was related to a higher miscarriage rate (relative risk 3.2). This study did not demonstrate any differences in perinatal death rates or in the prevalence of malformations among women working with organic solvents when compared with controls. In a recent case-referent study, the odds ratio of spontaneous abortions was increased by paternal exposure to several organic solvents, maternal exposure to organic solvents, and maternal heavy lifting.[50] The cohort was too small to evaluate the effect of these parameters or congenital malformations.

Discussing organic solvents will be incomplete without mentioning the fetal solvent (or gasoline) syndrome. In 1979 a syndrome of anomalies (hypertonia, scaphocephaly, mental retardation, and other central nervous system effects) was suggested in two children in a small American Indian community where gasoline sniffing and alcohol abuse are common.[51] Four other children had similar abnormalities, but in their cases it was impossible to verify gasoline sniffing. It is unclear what was the contribution of the lead in the gasoline or the alcohol abuse in producing these abnormalities. In another case a child with nearly classic fetal alcohol syndrome was born to a mother with major addiction to solvents, mainly toluene.[52] Heavy alcohol consumption also was reported in that woman, and the authors questioned a possible interaction between solvents and alcohol. Toluene embryopathy was described in two additional children whose mothers probably did not abuse alcohol.[53] Paint sniffing, namely toluene, resulted in severe renal tubular acidosis in five pregnant women.[54] Fetal heart rate tracing and dynamic ultrasonographic examinations were normal in four of five. Three neonates exhibited growth retardation, and two had anomalies and hyperchloremic acidosis. It is important to remember that the mothers in all these cases showed signs of solvent toxicity, indicating heavy exposure. In our experience this is not the case in most occupational exposures during pregnancy.

In summary, it appears that organic solvents may have the potential to induce congenital defects and other pregnancy complications. However, it is hard to prove or quantitate it, certainly not for solvents as a group. While fetal toxicity is biologically sensible in cases of intoxicated mothers, the evidence of fetal damage from levels that are not toxic to the mother is scanty, inconsistent, or missing.

Lead

The third most common occupational exposure in pregnancy encountered by us is lead. It accounted for 29 (0.6%) of the telephone consultations provided by the Motherisk Program during 1988. Three of them were followed up in our clinic (Tables I and II). The vast majority of lead exposures consisted of artists using glass staining or workers involved in paint manufacturing in the automotive and aircraft industries. Other occupational sources of lead exposure during pregnancy reported in the literature include the printing, smeltering, and battery industries.[55] Not only is lead an occupational hazard, but also it can enter the body from contaminated soil and drinking water,[56] by residence close to industrial areas or from a lead-exposed spouse,[57] and by consumption of moonshine whisky.[58]

Although it seems that blood lead levels in the United States are declining,[59] levels are now being considered toxic at a much lower range than in the past (<25 μg/dl in children, <50 μg/dl in adults).[60] Lead intoxication is still a hazard in the industrialized countries, including in the pregnant woman.

Lead crosses the placenta,[61, 62] possibly by both passive diffusion and active transport,[60] and it is unclear whether placental permeability to lead is constant throughout gestation.[61, 63-65] Transplacental transfer of lead has been shown in the human fetus as early as 12 to 14 weeks of gestation, along with increasing amounts of lead in fetal tissues with advancing gestational age.[66] Fetal bone and liver may have higher lead concentrations than maternal tissues.[67] Pregnancy, in a sense, is a stressor that may mobilize lead from maternal skeletal storage sites.[55] Iron and calcium deficiencies, both of which may exist in pregnancy, further increase the susceptibility to lead toxicity.

During the late nineteenth and early twentieth centuries women in the pottery and white lead industries used lead as an abortifacient.[55] European studies from that time found infertility, abortion, stillbirth, fetal death, and microcephaly to be associated with industrial lead exposure.[57, 68-71] Even paternal lead exposure was found as early as 1860 to affect fertility and viability of the offspring.[72] Wives of lead workers were reported to have more abortions, stillbirths, and premature births than in the general population.[57, 73] Consequently, the employment of women in plants involving a lead hazard was forbidden.[74] Although these studies should be evaluated with consideration of the high fetal and neonatal loss for other working women at that time,[75] most of the studies from the 1950s and later confirmed the early observations. For example, a study comparing the course and lead values in 249 pregnancies in Columbia, Mo., with 253 occurring at the center of America's lead belt at Rolla, Mo., showed that 96% versus only 70% were delivered at term.[76] In addition, 17% of the lead-exposed pregnancies had premature rupture of membranes, as compared with only 1% in the nonexposed group. Maternal and fetal blood lead levels in the cases of premature membrane rupture and preterm delivery were higher than in controls. A detailed Japanese study showed an increase in spontaneous abortion among female lead workers from a prelead rate of 45.6 per 1000 to 84.2 per 1000 (the rate in nonexposed employees was 59.1 per 1000).[77] A Danish study showed that when lead was used as an abortifacient, 60% of the pregnancies in the first trimester ended in abortion.[78]

A recent study from Boston (4354 cases) suggested lead to be associated, in a dose-related fashion, with an increased risk for minor anomalies.[79] The relative risk increased from 1.0 at 0.7 μg/dl to 2.73 at the level of 24 μg/dl. The anomalies discovered did not have a specific pattern and were of little health consequence. They included hemangiomas (14 of 1000 births), hydrocele (27.6 of 1000 male infants), minor skin anomalies (12.2 of 1000 births), and undescended testicles (11 of 1000 male infants).

Lead also affects the male gonads; chromosomal alterations, and abnormalities in sperm count, vigor, and morphologic features were demonstrated in workers and experimental animals.[80-82] Marital life records of lead-exposed men showed 24.7% of the marriages to be infertile compared with 14.8% in the nonlead control group. The rate of prematurity or stillbirth was 8.2%, whereas in the control group it was 0.2%.[82]

Although increased numbers of chromosomal aberrations (gaps, breaks, fragments, chromatid aberrations) have been reported in lead workers, it is still unclear what is the contribution of lead itself.[55]

Lead also seemed to have a small but demonstrable association with pregnancy-induced hypertension and elevated blood pressure at the time of delivery, but not with preeclampsia.[83, 84]

One of the main concerns regarding lead is its ability to cause neuropsychologic impairment in children. In the late 1970s 40% of children in the United States under 5 years of age had blood lead levels >20 μg/dl, and among urban black children the figure approached 60%.[85] At this level a variety of enzymatic and neurophysiologic processes are impaired. Until recently, it was unclear at what level deficits in children's learning and behavior become apparent and what is the contribution of in utero exposure. In a series of studies from Boston,[1, 2] blood lead levels and development were monitored in a group of urban children from birth to the age of 2 years. No infant had a cord blood lead level >25 μg/dl, the level that is regarded by the Centers for Disease Control as the upper normal limit for children. At all ages children whose cord level was >10 μg/dl scored lower in the Mental Development Index of the Bayley Scales (4.8 point difference between the low [<3 μg/dl] and high [≥10 μg/dl] groups). At the age of 6 months scores on the Psychomotor Development Index were not significantly related to cord blood lead level. Scores were not related to infants' postnatal blood lead levels. In a study from Cincinnati similar results were obtained.[86] This relationship between low-level lead exposure and neurobehavioral development was not confirmed in another study.[87] However, the mean cord lead level was 8.1 μg/dl, which is lower than the cutoff point of 10 μg/dl suggested by the Boston study. It is still unclear at what gestational age the fetus is most sensitive. However, because the fetal brain develops throughout gestation, it is conceivable that lead deposition at any stage may be detrimental.

These data suggest that low levels of lead delivered to the fetus may be toxic and may cause behavioral and developmental impairment. These levels are lower than the level defined by the Centers for Disease Control as acceptable for young children (25 μg/dl). Animal studies are consistent with these findings,[88-92] and it is possible that brain lead levels remain elevated longer than blood levels after short-term exposure.[93, 94] It is also possible that the fetus is more sensitive to lead than the young child. Possible mechanisms for the brain damage include interference with embryonic nutrition and energy supply, competition with cations such as zinc, iron, or calcium,[95] interference with mitochondrial function,[96] and synthesis of cytochromes, and effect on deoxyribonucleic acid synthesis.[97]

In a recent study we found that in Toronto about 90% of newborns had cord blood lead levels <3 μg/dl and none >10 μg/dl,[98] whereas in Boston about one third had such levels and one third had levels >10 μg/dl. This illustrates the difference between different urban environments.

The above data imply that it is important to detect, as early as possible, babies potentially exposed in utero to excess lead. Several studies documented a high correlation between maternal and cord blood lead levels.[61, 64, 99-101] In one of them mean cord levels were 10.1 μg/dl, compared with 10.3 μg/dl in the mother ($r = 0.6377$).[64] However, it is not advised to assume lead exposure throughout pregnancy from a single blood measurement, because of the changes in maternal blood levels and placental permeability to lead.[2] An alternative method to assess long-term lead exposure and estimate in utero exposure is head hair analysis, which reflects cumulative values.[102, 103]

On the basis of the higher susceptibility of the fetal brain to lead it may be argued that treatment should be instituted even when levels are lower than those accepted now as normal; however, the effectiveness of this approach has not been studied. More realistically, removal of the woman from the source of exposure is the first step. From the chelating agents available, BAL (dimercaprol) is a very toxic compound that has been shown to induce skeletal abnormalities in fetal mice.[104] In one pregnant woman with arsenic intoxication, after treatment in the sixth month of pregnancy a normal child was born.[105] Ethylenediaminetetraacetate is less toxic but it can chelate calcium, zinc, and other trace elements and may adversely affect the fetus. In one case it was given at the eighth month of gestation (at maternal level of 240 μg/dl) without complication.[75] The infant was normal with an undetected cord lead level. However, the sensitivity of the assay was very low (<60 μg/dl was undetectable). This infant had normal mental and developmental assessments at age 4. In another patient treated with calcium ethylenediaminetetraacetate at the same gestational age, it appeared that the treatment did not adequately reduce the infant's lead burden[106]; this child had a blood lead level of 60 μg/dl at the time of delivery and radiologic evidence of bony changes suggestive of prolonged exposure. D-Penicillamine is less effective than dimercaprol and calcium ethylenediaminetetraacetate, and in the doses used in lead poisoning it may cause connective tissue abnormalities (mainly cutis laxa) in human fetuses.[107] There is no experience with the use of the new oral chelators 2,3-dimercapto-succinic acid and dimercaptopropane-1-sulfonate in pregnancy. Since these chelators are less toxic, it is hoped that they will provide the answer to the question of the appropriate chelators in pregnancy. More critical research is needed to assess the need for treatment of low-level exposures, the criteria for instituting therapy and for assessment of response and the chelator of choice.

In the case of a woman occupationally exposed to lead, it is important to measure her blood lead concentrations and to compare them with the mean levels measured in the same city. In our practice several women working in glass staining had lead levels well below or near the mean recently determined by us for women in Toronto,[98] indicating that their lead load was within the expected. Should there be a substantially higher lead level in such patients, they would be advised to discontinue their occupational exposure.

In summary, of the three most common occupational chemical exposures in pregnancy, video display terminals do not represent a reproductive risk. Organic solvent may damage the fetal brain at high exposure levels, such as those encountered in substance abuse. There is no clear evidence to suggest that maternal exposure to allowable levels causes fetal damage. In the case of lead a dose-response fetal risk appears to have been established, and lead levels should be monitored to avoid fetal risk.

We thank Elizabeth Pellegrini, Donna Wood, Sheelagh Martin, and Natali Horlatch, from the Motherisk team, for their assistance in preparing this manuscript.

Effects of vibration frequency and tissue thickness on intrauterine sound levels in sheep

Douglas S. Richards, MD,[a] Robert M. Abrams, PhD,[a] Kenneth J. Gerhardt, PhD,[b] and Mary E. McCann, MA[b]
Gainesville, Florida

Pure-tone sinusoidal mechanical vibratory stimuli ranging in frequency from 4 to 4000 Hz were applied to the ventral abdominal wall of pregnant ewes, and intrauterine sound pressure levels were recorded with a hydrophone 5, 10, 15, and 20 cm from the surface. There were significant decreases in sound pressure levels with increasing frequencies ($p < 0.0001$) and increasing depth ($p = 0.01$). There was no significant interaction between these two variables. An electronic artificial larynx was also activated on the abdominal wall, resulting in quite high sound pressure levels (mean, 119 dB) measured 5 cm from the surface, with a significant decrease in sound pressure levels as the thickness of the intervening maternal tissues increased ($p = 0.005$). These results suggest that the frequency of vibratory stimulus used and the thickness of the maternal abdominal wall could influence fetal response to the vibroacoustic stimulation test by affecting intrauterine sound pressure levels. (AM J OBSTET GYNECOL 1991;165:438-42.)

Key words: Fetal sound, antepartum testing, acoustic stimulation, sheep

The vibroacoustic stimulation test has become popular as a test of fetal well-being. The factors that affect intrauterine sound pressure produced by the vibratory devices used for this test have not been adequately addressed. An understanding of these factors is important to develop testing procedures in which fetuses receive reproducible stimuli of appropriate intensity.

In an earlier study, Gerhardt et al.[1] reported high sound pressure levels produced by an electronic artificial larynx applied to the abdomen of pregnant ewes and recorded with a hydrophone sutured to the fetus. The sound pressure levels directly under the vibrator averaged 135 dB and decreased to 101 dB as the vibrator was moved 6 inches lateral from this point. In this study we concerned ourselves with two factors which could be expected to alter intrauterine sound levels in the vibroacoustic stimulation test: (1) the depth between the vibratory source applied to the surface of the abdomen of ewes and a hydrophone located inside the uterus and (2) the frequency of the stimulus.

Methods

Four near-term pregnant sheep were studied. Guidelines approved by the University of Florida for the care and use of animals were followed. The animals had been used for other experiments, then killed with an overdose of thiopental sodium and potassium chloride. Each animal was placed on its side, and the fetus was removed through a flank incision and hysterotomy. A miniature hydrophone (model 8103, Bruel & Kjaer, Marlborough, Mass.) supported on the end of a rigid Plexiglas acrylic rod was placed through the flank incision into the uterus, and the uterus was refilled with saline solution to remove air. The incision in the flank was made large enough so that the hydrophone could be moved in a direct line from 5 to 20 cm away from the ventral surface of the abdominal wall while maintaining its intrauterine position. The rod holding the hydrophone was held perpendicular to the table (Fig. 1).

Vibration excitation was produced by a shaker (model PM 50, MB Electronics, New Haven, Conn.) matched with a power amplifier (model 2250, MB Electronics). The shaker actuator rod was drilled and tapped to accommodate a circular stainless table (area, 1.32 cm^2) that was pressed against the ventral midline of the ewe with enough force to indent the skin by 1 cm. Sine waves were produced by a frequency generator (model 3010, Synascon Corporation, Chicago). Voltages driving the shaker were held constant at 2.5

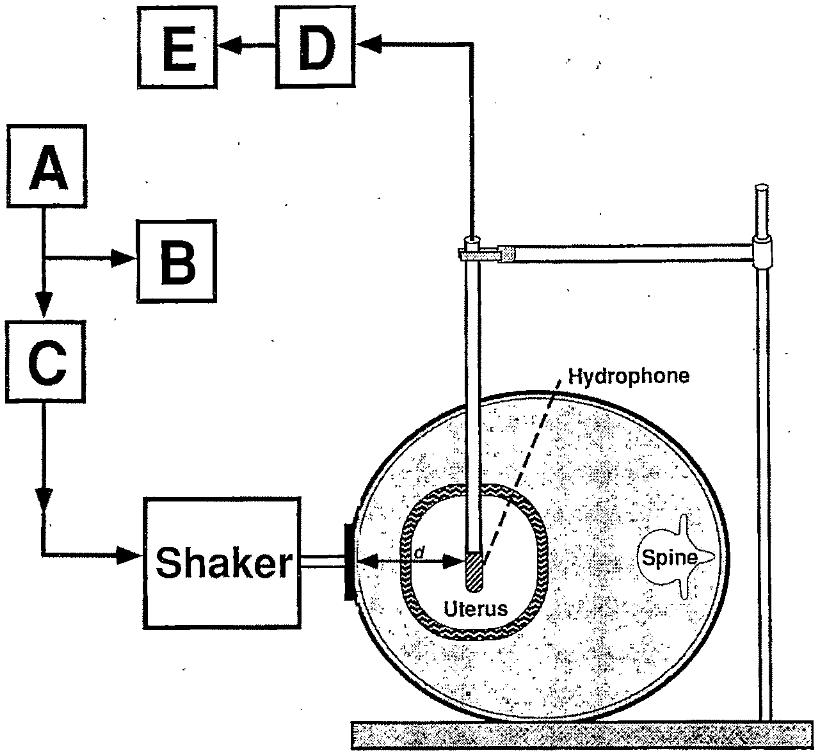

Fig. 1. Schematic drawing showing position of hydrophone within uterus and arrangement of devices for generating vibration and measuring sound pressure levels. *A,* Sine wave generator; *B,* frequency counter; *C,* power amplifier; *D,* charge amplifier; *E,* frequency analyzer; *d,* distance of hydrophone from shaker piston.

V between 4 and 500 Hz and at 7.5 V between 750 and 4000 Hz.

For each animal vibration at 17 different frequencies, ranging from 4 to 4000 Hz, was generated, first with the hydrophone 5 cm from the skin surface, then repeated with the hydrophone at depths of 10, 15, and 20 cm from the vibration exciter. At each depth, an electronic artificial larynx (model 5C, AT&T Consumer Products, Parsippany, N.J.) was also placed against the ventral abdominal wall overlying the hydrophone and activated.

The output from the hydrophone was amplified and conditioned with a charge amplifier (model 2635, Brull & Kjaer) and fed into a real-time frequency analyzer (model 2123, Brull & Kjaer). For pure-tone vibration, at each frequency and distance the sound pressure level (20 μPa) in 1/24 octave bands were measured at the fundamental frequency and first harmonic. The overall sound pressure level was recorded on linear scale, which is a measure of the sound pressure across the entire spectrum. Sound pressure levels were corrected for the higher voltages used to drive the vibration exciter at the higher frequencies. In the analysis of the levels produced by the electronic artificial larynx, only the linear value was used, because this device produces vibration across a wide range of frequencies.

The effects of vibration frequency and hydrophone depth on sound pressure levels were analyzed by repeated measures analysis. The effects of hydrophone depth on levels produced by the electronic artificial larynx were studied independently, with repeated measures analysis.

Results

For the electronic artificial larynx there was a statistically significant decrease in sound pressure level as the depth of the hydrophone increased from 5 to 20 cm (Fig. 2) ($p = 0.005$). The average fall in sound pressure level was from 119 dB at 5 cm depth to 102 dB at 20 cm.

With pure-tone vibration, analyzed at the fundamental frequency, there was a marked inverse relationship between vibration frequency and the resultant sound pressure level ($p < 0.0001$) (Fig. 3). The mean sound pressure level at a depth of 5 cm fell from 144 dB at 4 Hz to 101 dB at 4000 Hz. A similar fall was observed at all other depths. There was a less marked, but statistically significant, inverse relationship between

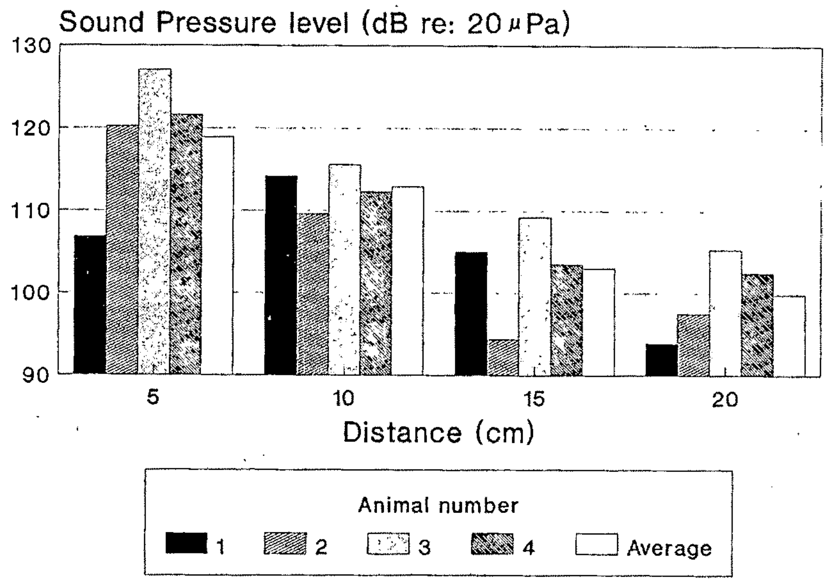

Fig. 2. Intrauterine sound pressure levels produced by electronic artificial larynx.

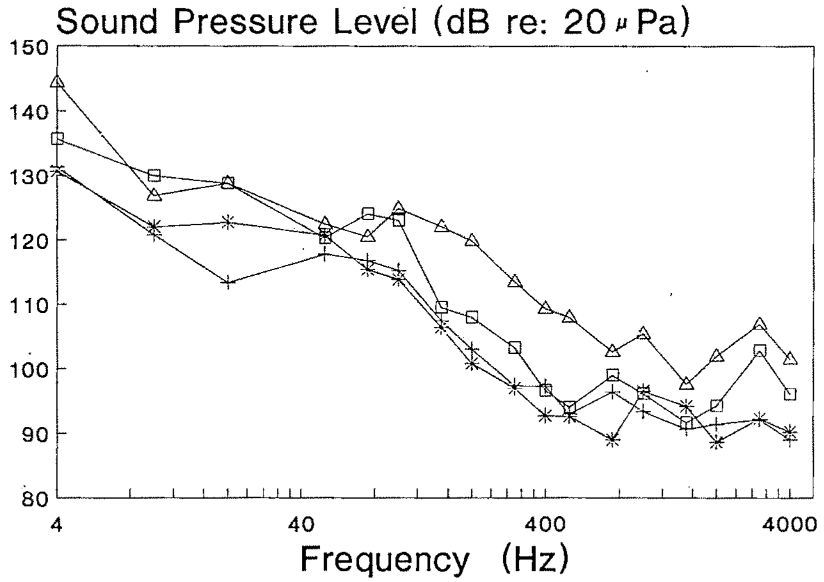

Fig. 3. Average intrauterine sound pressure levels recorded with hydrophone at different depths, generated by sinusoidal pure-tone vibration. △, 5 cm; □, 10 cm; +, 15 cm; *, 20 cm.

hydrophone depth and the sound pressure level produced ($p < 0.01$). The mean level dropped from 114 to 104 dB as the distance was increased from 5 to 20 cm. There was no observed interaction between frequency and distance ($p = 0.56$); that is, the observed drop with increasing distance was no greater at high frequencies than at low frequencies.

There was only an average 1.9 dB difference between the linear sound pressure level and that at the fundamental frequency, indicating that most of the transmitted vibrational energy was contained in the fundamental frequency. This finding was constant across frequencies. Sound pressure level measured at the first harmonic also decreased significantly as the frequency of vibration increased ($p < 0.0001$). The difference between the sound pressure level at the fundamental frequency and at the first harmonic became increasingly greater as the frequency of the input increased ($p < 0.0001$).

Comment

This study was designed to investigate the effects of vibration frequency and thickness of intervening maternal tissues on intrauterine sound levels produced by vibroacoustic devices applied to the abdomen. Knowledge about factors such as these will aid in the development of a vibroacoustic stimulator that produces intrauterine sound levels that are reproducible from one pregnancy to another and are within a desirable intensity range.

The characteristics of the ideal vibroacoustic stimulator have not yet been determined. Studies by Kisilevsky et al.[2] and Yao et al.[3] have shown that there is an incremental response of fetuses to stimuli of increasing intensity. It stands to reason that a fetal response test will be more interpretable if the intrauterine sound levels produced by a vibroacoustic device are similar in different women. If a given stimulator produces unusually high intrauterine sound levels in some women, their fetuses may respond with unphysiologic state changes of uncertain significance. If, on the other hand, a given stimulator produces sound pressure levels of insufficient intensity to elicit the desired state changes in the fetus, the test could inappropriately be interpreted as abnormal.

Previous clinical studies of vibroacoustic stimulation have not adequately addressed the question of intrauterine sound levels.[4, 5] The electronic artificial larynx is the stimulus source most commonly used in clinical practice, apparently because of its low cost, portability, and availability, not because of scientific evidence demonstrating that the type of stimulus it produces is ideal for its intended purpose. It may, in fact, produce too intense a stimulus, as demonstrated by Visser et al.[6] They showed that stimulation with the electronic artificial larynx produced unphysiologic disorganized states in the fetus, rather than bringing about a change from state 1F to 2F as is seen in a spontaneously reactive nonstress test. The current study confirms the previous work by Gerhardt et al.[1] showing that sound pressure levels produced by the electronic artificial larynx in the sheep uterus are much higher than those measured in air and quoted in the largest clinical studies.[7, 8] Since the electronic artificial larynx is a vibromechanical device designed to transmit sound pressure more efficiently through tissue and fluid than through air,[9] the determination that it produces approximately 82 dB sound pressure level measured at 1 m in air[7, 8] hardly seem relevant to estimating intrauterine levels.

Gerhardt et al.[1] showed in an earlier study that the intrauterine sound pressure level in the ewe varied from an average of 135 dB directly over the hydrophone to 101 dB when the electronic artificial larynx was moved 6 inches laterally on the skin surface. In this study we showed that with the electronic artificial larynx remaining fixed over the hydrophone, increasing the depth of the hydrophone from 5 to 20 cm decreased the mean sound pressure level from 119 to 102 dB. The difference in the maximum sound pressure level in the two studies is probably explained by the fact that in the earlier study the center point was determined by searching for the spot producing the highest sound levels, whereas in the current study it was determined from the geometry of the hydrophone stand (Fig. 1). Also, the depth of the hydrophone was <5 cm in the previous study. The clinical implication of these studies is that, in attempting to achieve a reproducible intrauterine stimulus, the thickness of the intervening tissues does not appear to be as important a factor as the location of the vibroacoustic device on the skin surface. This finding needs to be replicated in human studies.

Sound transmission loss through solid materials has been well characterized by structural engineers.[10] In general, energy in the form of sound or vibration is transmitted through solids more readily at lower than at higher frequencies. Sound transmission loss through animal tissues has been thoroughly studied for ultrasonic frequencies,[11] but there is very little information available on the transmission of vibration in the audible and subaudible frequency range. The complexity of the abdominal wall and organs in large animals, with varying resistive and resonant properties of the different tissues, makes precise predictions of intrauterine sound pressure levels from externally applied vibration impossible. However, as expected by the generally observed behavior of vibration in solids, intrauterine sound pressure levels generated with a vibration exciter was found to be greater at low frequencies. The clinical significance of this finding is that if a high-frequency stimulator is used for the vibroacoustic stimulation test, more voltage will have to be applied to achieve the same sound pressure levels as those achieved at low frequencies.

In normal pregnancy the uterus also is occupied by a fetus and placenta of varying dimensions that may reflect, absorb, or transmit vibrations. It should be noted that the experimental design we used, in which the fetus was removed, may result in different absolute intrauterine sound levels compared with those of a live fetus and an intact pregnancy. However, in a live animal the same progressive fall in sound levels with increasing depth and frequency would be expected.

We expected to find that with progressively increasing distances between the vibration exciter and hydrophone, sound pressure levels would fall off much more at high frequencies than at low frequencies. We postulated that a low-frequency vibroacoustic stimulator would therefore result in a more reproducible intrauterine stimulus, at varying distances, than a high-frequency device. Our results did not support this hypothesis, since the difference between the sound pressure levels at 5 and 20 cm were no greater at high frequencies than at low frequencies. Contrary to our expectations, our experiments did not support the idea that in the clinical application of a vibroacoustic stimulation test low-frequency stimuli would result in more reproducible intrauterine sound pressure levels. Our results may have been different if, rather than increasing the distance from the shaker to the hydrophone by moving the hydrophone within the abdominal cavity, we had used a model where the actual thickness of the abdominal wall was increased. Investigations in humans, with subjects of varying degrees of obesity, are needed to further evaluate possible interaction between vibration frequency, abdominal wall thickness, and intrauterine sound pressure levels.

We acknowledge with gratitude the many helpful comments by David J. Burchfield, MD, and Calvin C. Oliver, PhD.

The interaction of electrosurgical bipolar forceps and generators on an animal model of fallopian tube sterilization

Robert D. Tucker, PhD, MD,[a] Jo Ann Benda, MD,[a] Ali Mardan, PhD, MD,[a] and Tibor Engel, MD[b]

Iowa City, Iowa, and Denver, Colorado

Electrosurgical tubal sterilization with bipolar forceps has shown a variable and, in certain studies, a high failure rate. Some physicians have questioned if failure rates are due to an incompatibility between bipolar forceps and bipolar generators of different manufacturers. This manuscript presents data on tissue desiccations performed on a rat uterine horn model that uses two bipolar forceps of quite different designs and two popular bipolar generators. The data demonstrate that if an appropriate amount of energy, between 100 and 117 J, is applied to the tissue, consistent destruction occurs, regardless of the generator-forceps combination used. Histologic examination of the desiccated uterine horns displayed complete occlusion of all samples 8 weeks after the procedure. However, immediately and at 3 weeks after the procedure patent uterine horns were found. In the patent samples most samples displayed considerable electrosurgical damage. (AM J OBSTET GYNECOL 1991;165:443-9.)

Key words: Bipolar, electrosurgical, sterilization

During the last two decades, radio-frequency electrosurgical sterilization through the laparoscope has become a popular method for permanent female sterilization. Initially the procedure was performed by desiccation of several segments of the fallopian tube by monopolar electrosurgical forceps. When the procedure is performed in this fashion, the current flows from both tines of the forceps through the fallopian tube to a return electrode on the buttocks or thigh of the patient. Although this method is effective in producing permanent sterilization, persistent complications, including return electrode burns and alternate site burns in the abdominal cavity, e.g., bowel burns,[1-4] led Corson et al.[5] to suggest substituting bipolar forceps for monopolar forceps in electrosurgical laparoscopic sterilization.

In bipolar electrosurgery the radio-frequency current flows from one tine through the tissue to the second tine; this eliminates the return electrode with all the associated return electrode burns and virtually all alternate site burns. With the goal of improving patient safety, several researchers and companies introduced bipolar laparoscopic forceps,[6, 7] and the use of these various forceps has gained acceptance. Most groups have reported pregnancy rates similar to those after monopolar sterilizations[8]; however, several groups have reported an unexpectedly high incidence of pregnancy, from 4%[9] to 16%,[10] after bipolar sterilization.

Speculation as to the cause of these failures includes the low voltage of a bipolar output causing incomplete tissue destruction,[9] delayed fibrosis and tubal occlusion in bipolar procedures,[10] and generator-to-forceps mismatch.[11] This manuscript presents data showing that if sufficient energy is delivered into the tissue, successful tissue destruction can be accomplished, regardless of which generator or forceps combination is used.

Methods

The rat uterus was chosen to approximate the human fallopian tube. Rats possess a bifid uterus, each horn of which is the same approximate diameter as the central section of a human fallopian tube. Nonpregnant Sprague-Dawley rats weighing between 275 and 300 gm were used in the study. Each horn of the uterus could be coagulated once without causing significant postsurgical adhesions. Guidelines for the care and use of experimental animals was institution approved.

Uterine horns were examined histologically at four postsurgery intervals: immediately, 3 weeks, 8 weeks, and 12 weeks. Each time-interval group was treated identically. The groups consisted of 32 rats. Equal numbers of rats in each group were treated with a different combination of electrosurgical generator-forceps: Valleylab SSE2L generator and Storz forceps, Valleylab SSE2L generator and Kleppinger forceps, Wolf generator and Storz forceps, Wolf generator and Kleppinger forceps. Therefore eight rats in each time-interval group had bilateral uterine horn desiccations per-

formed with each of the four generator-forceps combinations. This resulted in 16 actual uterine burns to evaluate from each of the generator-forceps combinations.

The rats were anesthetized with intraperitoneal injection of sodium pentobarbital (50 mg/kg). The uterus was viewed by a small midline incision. After each horn of the bifid uterus was desiccated once, the uterus was removed (immediate group) or the incision was closed with either staples or suture, and the animals were allowed to recover.

The tubal desiccations were performed with a single application of the forceps to each uterine horn. Power was applied continuously until the standard visual end point was reached. As the uterine horn desiccated, it would swell, blanch, and collapse with a dry appearance; at this point the power application was terminated. The visual end point was noted in all animals.

The technique of the application of the Kleppinger forceps to the uterine horn deserves comment. As designed, the flat duckbill tongs of the instrument grasp the mesosalpinx while the curved portion surrounds the tube. The intent is to destroy the tube and the associated blood supply simultaneously. Some physicians also recommend repositioning the forceps' duckbill over the previous tube desiccation site to deliver a second coagulation.[10, 12] Placing the curved portion around the uterine horn could not be performed on the rat as the flat duckbill tongs would short to each other without desiccating the tube, because the small amount of thin mesosalpinx-like tissue on the rat uterine horn. Therefore the flat duckbill tongs were placed directly on the horn for a single coagulation.

The Wolf generator output is a pure sine wave alternating current; therefore the Valleylab SSE2L was tested in the bipolar "cut" mode, which also has a pure sine wave output. The Wolf generator was used on a setting of 6 and the Valleylab generator at a setting of 4; these settings correspond to approximately 50 W power into a 100 Ω load. The electrosurgical generator voltage, the radio-frequency current supplied to the tissue, and the corresponding power delivered to the tissue were measured by a demodulator circuit, which was previously described.[13] The three values were measured over time and recorded on an oscillographic recorder. A typical set of voltage, current, and power traces is shown in Fig. 1. The power was not constant but varied with time; therefore the total energy delivered into the tissue was calculated by multiplying the measured power by the time, i.e., Energy = Power × Time (where the units are energy in joules, power in watts, and time in seconds).

The rats were killed, and the entire uterus was removed and fixed in 10% formalin for at least 24 hours. For the immediate group and the 3-week group, the desiccated segment and a normal segment of each uterine horn were embedded in paraffin. For the immediate group, cross sections of the uterine horn were examined; for the 3-week group, cross sections were cut; and for the 8-week group, longitudinal sections were cut. All histologic samples were stained with hematoxylin-eosin stain. The histologic sections were examined without knowledge of the burn technique by a surgical pathologist (J.A.B.).

The immediate group was examined for evidence of tissue damage in the uterine horn epithelium, muscle layer, and surrounding soft tissue. Vascular damage and fat necrosis also were noted. Four measurements were performed on each horn sample: the normal horn diameter, the normal lumen diameter, the desiccated horn diameter, and the desiccated lumen diameter. From these measurements the percentage decrease in the diameter of the horn and the lumen was calculated.

The 3- and 8-week groups were examined for the patency of the horn lumen, scarring of the muscle layer, and fat necrosis. The vessels were examined for thrombosis, occlusion, recanalization, reendothelialization, fibrinoid necrosis, and coagulation necrosis.

The remaining 12-week group was simply examined by gross dissection for loss of segment in the desiccated section of the uterine horn.

Results

Although the generators were set at the same approximate power settings, the oscillographic recordings of the power delivered to the tissue varied dramatically. Neither generator supplied a constant power to the tissue over time (Fig. 2). For a given generator-forceps combination the power delivered varied from uterine horn to uterine horn, some horns required low power for a long period of time whereas others required high power for a short period. The power variations were substantial: The Wolf generator maximum powers varied from 11.2 to 28.8 W, while the Valleylab generator maximum powers varied from 18.2 to 29.9 W. The variations both in maximum power and in power levels over application time necessitate the calculation of the total energy applied over the treatment period.

The total energy delivered to the tissue and the total desiccation time among the four groups evaluated did not statistically differ. Therefore the energies and desiccation times for the four time-interval groups were evaluated together for each generator and forceps combination. Thus there are 32 animals or 64 uterine horn burns in each of the four combinations, yielding a total of 256 horn desiccations. Comparisons of the average energy used for uterine horn desiccation were made for each of the four generator and forceps combinations (Table I): (1) Wolf-Storz versus Wolf-Kleppinger, (2) Valleylab-Storz versus Valleylab-Kleppinger, (3) Wolf-Storz versus Valleylab-Storz, and (4) Wolf-Kleppinger versus Valleylab-Kleppinger. The average time rquired to complete the desiccation to a visual end point also was compared for each of the four generator and forceps combinations. Of the eight energy and time comparisons, only three were statistically significant: (1) the Storz-Wolf versus the Kleppinger-Wolf energy comparison, (2) the Kleppinger-Wolf versus the Kleppinger-Valleylab energy comparison, and (3) the Kleppinger-Wolf versus the Kleppinger-Valleylab desiccation time comparison. Although the data display highly significant p values, the actual averages are relatively similar with variations of approximately 10% to 15% in total energy and only 1 second or 10% in application time.

In the immediate group, 16 uterine horns (eight animals) were examined for each of the four generator-forceps combinations. The data are summarized in Table II. The diameter of horn and lumen for normal and treated groups was measured, and the ratio of diameters for treated versus normal was calculated. In comparing the horn and lumen ratios for the Storz

*Statistically significant.

versus the Kleppinger forceps with the use of a given generator, three of the four comparisons were statistically significant at levels of $p < 0.002$, and the remaining combination tested at $p = 0.056$. The nonsignificant value, the lumen diameter comparison of the Storz versus the Kleppinger forceps with the use of the Valleylab generator, was strongly influenced by large variations in the treated lumen diameter; two horns showed increases in the lumen diameter after treatment.

Only one of the four comparisons between generators for a given forceps tested significant. This was the comparison of horn diameter with the use of the Kleppinger forceps for the Wolf versus the Valleylab generator, $p = 0.22$ (Table II). In the short term the Kleppinger forceps, used as described in the Methods section, displayed reduced tube and lumen diameter after treatment over the Storz forceps when used with either generator.

Of the 64 uterine horns in the immediate group, only 26 displayed complete occlusion (Fig. 3). However, all horns displayed full-thickness damage, including both epithelial and muscle damage as a result of the electrosurgical desiccation. The great majority displayed soft tissue damage, coagulated blood vessels, and necrosis in the surrounding fat. A typical patent horn with electrosurgical damage is displayed in Fig. 4. Both generators, as previously described, caused more acute damage with the Kleppinger forceps than the corresponding generator with the Storz forceps.

In the 3-week group, two of the 64 uterine horns that were examined histologically were patent. The pa-

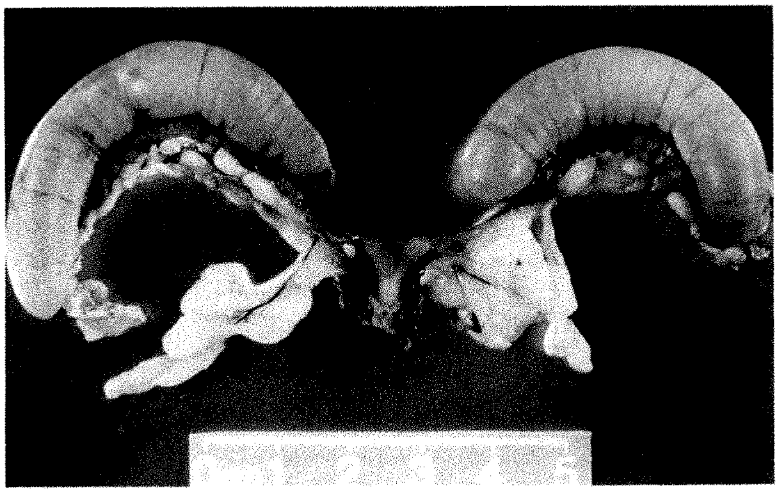

Fig. 5. Entire bifid uterus from animal in 12-week group. Both horns display missing segment at area of electrosurgical desiccation. Remainder of horn is dilated.

tent horns had desiccations performed with (1) the Kleppinger forceps and the Valleylab generator and (2) the Storz forceps and the Wolf generator. The tissue section from the Kleppinger-Valleylab combination did show muscle scarring, fat necrosis, and vessel fibrinoid necrosis. The section from the Storz-Wolf combination displayed little destruction, either grossly or histologically. In both of these cases the horn on the opposite side was identified as not patent.

In the 8-week group, all 64 gross samples displayed a loss of a segment of uterine horn, which is assumed to have undergone resorption. No histologic sample displayed patency. Procedure energies and times were not statistically different from those of the other three treatment groups.

The remaining 12-week group was examined grossly (Fig. 5). In all cases a segment of the uterine horn was absent and was assumed to have undergone necrosis and resorption. The average energies and desiccation times were virtually identical to those of the immediate, 3-week, and 8-week groups. In all cases except one, both ends of the horn were stenotic and closed. The exception was a desiccation performed with the Kleppinger-Wolf combination. In this case the treated area was absent, but one end of the surviving horn was patent with a relatively normal-appearing lumen. The adjacent end was closed.

Comment

While use of bipolar electrosurgical tubal sterilization has decreased associated burn complications, many groups have reported an increased incidence of sterilization failure. One explanation of these failures has been the mismatch of forceps and generator. Should a given vendor combination be truly matched, the substitution of another generator or forceps would present important medical and legal complications and less predictable surgical outcome.

The data presented in this manuscript suggest little clinical importance to generator-forceps combination. While statistical differences were shown in the total energy required and the length of time required for complete visual desiccation, the differences were only 10% to 15%. The largest average time variation was only approximately 1 second.

Although both generators were set for approximately 50 W output power, the maximum power output during the procedures was <30 W for both generators. This is a result of the generator output power being specified by the manufacturer into a constant value pure resistance. The tissue, however, is not a pure resistance but has a component of capacitance as a result of cell membranes. (Capacitors store energy.) The value of tissue resistance is also constantly increasing during the procedure as the tissue desiccates. The data demonstrate that 11.2 to 29.9 W was adequate to provide the needed tissue destruction; however, lower powers required longer application times.

The data demonstrated that most horns were patent immediately after a procedure, regardless of which generator-forceps combination was used, although the damage in all samples was extensive. At 3 weeks two of 64 horns were patent. One of these patent samples displayed extensive damage, whereas the other sample displayed little damage. At 8 weeks all lumina were closed. In the 12-week group one horn had a patent distal end, a relatively normal-appearing lumen, and a closed proximal end. With the assumptions that the extensively damaged horn from the 3-week group would ultimately fibrose and close and that the patent horn in the 12-week group was nonfunctional because the proximal end was closed, the only failure would be the horn from the 3-week group that displayed little damage. This would represent only one failure in the series of 256 uterine horn desiccations, for a failure rate of 0.4%. If all three of these horns were considered failures, the rate would be 1.2%. Thus a failure rate, although small, can be expected, even with accurately measured energy delivery. This finding underscores the need for alternative contraceptive methods for at least 8 weeks after a procedure.

The various forceps did display differences in their ability to reduce both the horn and lumen diameter immediately after a procedure. The Kleppinger forceps significantly reduced both horn and lumen diameter when used with either generator. This is likely a result of the compressing action of the wide duckbill that was applied directly to the uterine horn, as previously described in Methods.

The data presented suggest no necessity to match a particular generator to a particular forceps and that successful tissue destruction can be performed with any of the generator-forceps combinations. The radio-frequency currents produced by bipolar forceps are confined to flow over a smaller tissue volume than are those of monopolar forceps. Therefore adequate tissue injury would require a longer current application time. One can only speculate that failure to apply radio-frequency current for a sufficient amount of time could lead to incomplete destruction in the reported failures.

Our data demonstrated that the visual end point was reproducible in both measured time and energy. However, in laparoscopic procedures the clinical end point of "blanch, swell, and collapse" may be more difficult to evaluate than in our open surgical model. To achieve tissue destruction, radio-frequency current must be passed for an adequate time period. Without a good visual end point, defining an adequate time period becomes difficult. At present, there is no clinical or electrical option for measuring energy delivered to the tissue. The Wolf generator provides an ammeter to monitor the radio-frequency current. However, Wolf recommends that the meter be used to test electrical continuity, i.e., to test that the circuit is complete. Some physicians use the circuit to monitor the end point of the tube desiccation; however, this technique is not without potential failure. It is possible to monitor current flow through the meter without flow through the tissue; this could occur if the forceps tines short or touch through a hole in the mesosalpinx. It is also possible for the meter to show reduced current flow without complete tube desiccation by retaining small amounts of dried tissue on the forceps from a previous application. A true measure of complete tube desiccation would require monitoring changes in either the tissue resistance or the energy delivered to the tissue; nothing commercially available will perform this function.

Many variables also affect the time required to achieve adequate tissue destruction. Lower power settings will require longer generator activation time than will higher power settings. Coagulation and blend waveforms produce less power at a given setting than does a cut waveform and thus require longer activations. At a given power setting thicker tissue also will require longer time periods. Differences in blood flow and tissue composition also will affect the rate of tissue desiccation. With these potential variables and, at present, a visual end point as the measure of adequacy, it is important to apply radio-frequency current to several contiguous sites to achieve adequate tissue destruction.

The application of the Kleppinger forceps also deserves comment. The duckbill portion was designed to desiccate the mesosalpinx containing the blood supply to the fallopian tube. The curved forceps portion is designed to surround the tube and apply simultaneous current. During this typical application it is possible that the flat duckbill portion becomes electrically shorted and the majority of the current passes between the flat tines. Subsequently little current passes through the fallopian tube, thus resulting in inadequate tissue destruction. Therefore we agree with the recommendation that an additional desiccation of the fallopian tube with the flat duckbill section be applied after the initial simultaneous current application to both tube and mesosalpinx. This procedure has previously been advocated by Kleppinger.[14]

Our data show that hardware available for electrosurgical bipolar tubal sterilization is adequate to apply sufficient power for an adequate amount of time (e.g., total energy) to destroy tissue of similar composition and size of the human fallopian tube.

Fetal hypertension induced by norepinephrine infusion and umbilical artery flow velocity waveforms in fetal sheep

Hans van Huisseling, MD, Guido J.J.M. Muijsers, MD, Jelte de Haan, MD, PhD, and Tom H.M. Hasaart, MD, PhD
Maastricht, The Netherlands

This study was designed to examine the effects of fetal hypertension on the umbilical artery pulsatility index. Fetal arterial blood pressure and umbilical venous pressure were measured in eight sheep, 3 to 5 days after surgery. Umbilical blood flow was measured with an electromagnetic flowmeter around the common umbilical vein. Umbilical artery flow velocity waveforms were obtained either by an indwelling 5 MHz pulsed Doppler device ($n = 4$) or transcutaneously by a 4 MHz continuous-wave Doppler device ($n = 4$). Fetal blood pressure was raised by intravenous infusion of norepinephrine 10 μg/min during 5 minutes. Norepinephrine infusion resulted in elevated arterial and umbilical venous pressures, accompanied by a bradycardia during the first 3 minutes. Umbilical blood flow, calculated placental vascular resistance, and umbilical artery pulsatility index did not change. After atropine administration, the norepinephrine-induced elevated arterial and umbilical venous pressures were accompanied by tachycardia, increased umbilical blood flow, and no change in placental vascular resistance and umbilical artery pulsatility index. It is concluded that fetal arterial hypertension provoked by norepinephrine infusion has no effect on placental vascular resistance, umbilical blood flow, and umbilical artery pulsatility index. (AM J OBSTET GYNECOL 1991;165:450-5.)

Key words: Placental vascular resistance, norepinephrine, infusion of; pulsatility index, umbilical artery; hypertension, fetus

Since the introduction of Doppler ultrasonography in the study of the fetal circulation by Fitzgerald and Drumm[1] more than a decade ago, an overwhelming number of articles about umbilical artery flow velocity waveforms have been published. Initial reports showed promising results concerning the capability of umbilical artery velocimetry to detect intrauterine growth restriction and to predict fetuses with poor perinatal outcome.[2-5] Later studies questioned the validity of umbilical waveform analysis with regard to the detection of intrauterine growth restriction and compromised fetuses.[6-9] In a case of an abnormal umbilical artery waveform, it is suggested that the fetus may be seriously ill. On the other hand, a seriously ill fetus may have a normal umbilical artery waveform.[7] Abnormal waveforms can be seen already in growth-retarded fetuses several weeks before the occurrence of fetal heart rate decelerations as a sign of fetal hypoxia.[2] In contrast, we have shown in fetal sheep that moderate and severe fetal hypoxia can exist without any effect on umbilical artery waveform indices.[10-13] Therefore analysis of the umbilical artery waveform does not seem to give adequate information as to what extent fetal reserve capacity and compensatory mechanisms are mobilized. This view is supported by a recent article of Block et al.,[14] in which study the observed distribution of regional blood flow in fetal sheep was not different during imposed acute hypoxemia in fetuses with normal placentas compared with fetuses in which intrauterine growth restriction was created by umbilical embolization. Hypoxic stress results in a release of catecholamines, mainly norepinephrine, which has a predominant α-adrenergic receptor–stimulating effect. Through α-receptor stimulation, fetal cardiac output redistribution occurs, which is essential for an adequate supply of oxygen to high-priority organs such as brain and heart during hypoxemia.[15, 16] Norepinephrine infusion causes an increase of systolic, diastolic, and mean arterial pressure in the fetal circulation,[17, 18] with secondary effects on fetal heart rate or umbilical blood flow.[19] The influence of fetal hypertension on the umbilical artery velocity waveform is not known. The aim of this study was to investigate the effect of norepinephrine-induced increased fetal arterial blood pressure on the umbilical artery flow velocity waveform. Fetal blood pressure was raised by intravenous infusion of norepinephrine. The umbilical artery flow velocity waveform was described by the pulsatility index, according to Gosling et al.[20]

Material and methods

Surgery. The experiments were carried out in eight ewes of the Dutch Texel breed, 3 to 5 days after surgery, between 113 and 124 days' gestation (term, 147 days). Surgical instrumentation was carried out under aseptic conditions and with the animal under general anesthesia, induced with pentobarbital sodium and maintained with 1% halothane in a 2:1 mixture of nitrous oxide and oxygen, and involved insertion of a catheter in the distal aorta through a femoral artery, a catheter in a femoral vein for drug infusion, a catheter in a major umbilical vein through a cotyledonary vein, placement of an electromagnetic flowmeter around the intraabdominal common umbilical vein, and placement of an inflatable balloon occluder around the umbilical cord at the site of the abdominal insertion for in vivo zero blood flow calibration. A 5 MHz pulsed Doppler device was placed around one of the two umbilical arteries. Anesthetic technique and surgical instrumentation has been extensively described previously.[10, 21] The surgical and experimental procedures were approved by the local animal medical ethics committee.

Measurements. Blood flow in the common umbilical vein was measured with a Skalar Transflow 601 flowmeter system (Skalar, Delft, The Netherlands). Fetal arterial blood pressure and umbilical venous pressure were determined with the zero point at the level of the ewe's spine. Fetal heart rate was calculated from the pulse of the arterial blood pressure wave. All signals were led to amplifiers (Hewlett Packard 8800 series, Hewlett Packard, Andover, Mass.), displayed on a monitor and an eight-channel strip chart recorder, stored on magnetic tape, digitized, and analyzed with a computer. Umbilical artery waveforms were obtained by the 5 MHz pulsed Doppler probe around one umbilical artery in four animals. Because of malfunctioning of the 5 MHz indwelling Doppler probe, umbilical artery velocity waveforms were obtained by a 4 MHz continuous-wave Doppler device (Delalande Electronique, Courbevoie, France) in the other four animals. The ultrasonographic beam was insonated from the abdominal skin of the standing ewe after visualization of the umbilical cord by ultrasonography (Scanner 400, Pie Medical, Maastricht, The Netherlands). The origin of the received signals was verified by comparison with fetal heart rate, derived from the arterial pressure waveform, and by presence of oppositely directed venous blood flow velocities within the Doppler sample volume. The Doppler frequency shift signals were stored in quadrature on analog tape, synchronously with the other signals for off-line analysis. After transformation of the Doppler shift signals by a spectrum analyzer (Doptek Ltd., Chichester, England), pulsatility index values were obtained by drawing the maximum envelope curves of the frequency-shift spectra with a hand-guided light pen. In the group of fetuses in which the continuous wave Doppler device was used, it was not always possible to obtain representative umbilical artery velocity waveforms at every point of time. Nevertheless, velocity waveforms were obtained in all animals at 4 and 5 minutes of infusion.

Experiments. The animals were allowed to recover for 3 to 5 days after surgery. After baseline conditions were established during 1 hour, norepinephrine was infused by an infusion pump (No. IP3H; Vicker Ltd., Basingstoke, England) at a rate of 10 μg/min during 5 minutes in eight fetal sheep with the autonomic nervous system intact (group 1). To eliminate the baroreceptor effect of the norepinephrine-induced hypertension on the fetal heart rate, cholinergic blockade was established by atropine at a dose of 1 mg/kg estimated fetal weight (group 2). Each animal was used in two protocols, one without atropine and one after atropine administration on different days after randomization. Ten minutes before and 10 minutes after the experiments an arterial blood sample was drawn for analysis of fetal P_{O_2}, P_{CO_2}, and pH.

Calculations and data analysis. The mean values for the hemodynamic variables were assessed over 10-second periods, at 1 minute before infusion (control period), at every minute during the infusion, and at 5 minutes after the infusion. Mean umbilical artery pulsatility index was calculated over five consecutive heart cycles that occurred during these 10-second intervals. Placental vascular resistance was defined as the difference between fetal arterial pressure in the distal aorta and venous umbilical pressure divided by umbilical venous blood flow. Statistical analysis was performed for each variable on the pooled values from each animal by comparing the control values before infusion with the values during and after the infusion by means of a paired Student *t* test with Bonferroni correction for repeated analyses.[22] In those cases in which umbilical artery velocity waveforms, at the various points of time, could not be obtained in all eight animals, comparisons were made between the reduced number of values during the infusion period and their respective control values. A p value of <0.05, after Bonferroni correction, was taken to represent statistical significance. The values of the fetal arterial acid-base balance were compared before and after norepinephrine infusion with a paired Student *t* test. Mean values ± SE are reported.

Results

Intact autonomic nervous system (group 1). The absolute values of the fetal cardiovascular variables during the control period for the animals with intact autonomic nervous system (group 1) and after atropine administration (group 2) are shown in Table I. Fig. 1 shows the effects of norepinephrine infusion on the

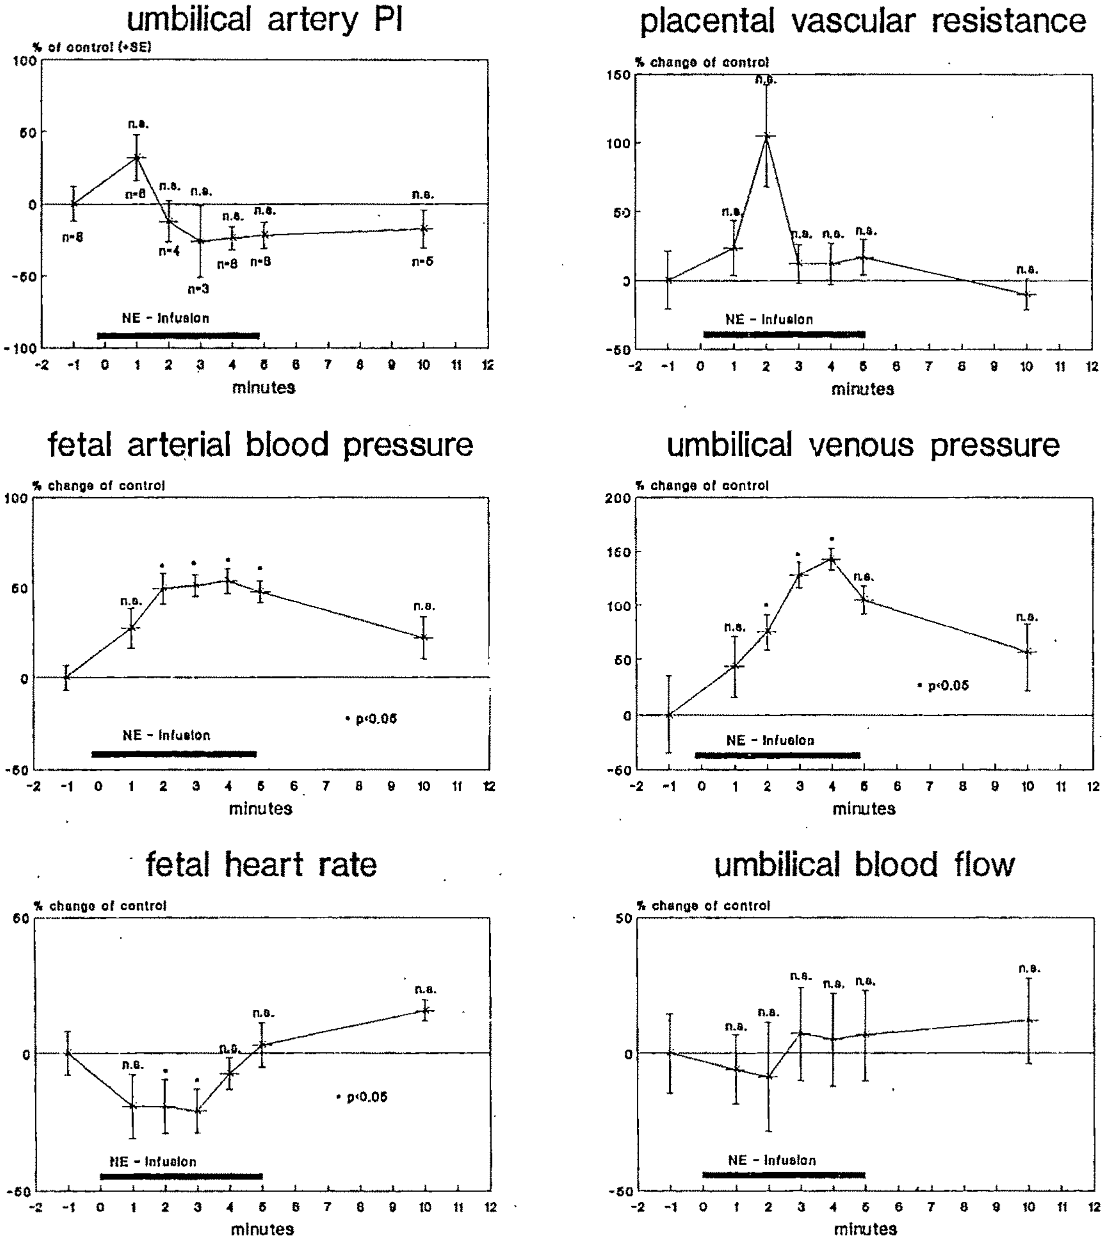

Fig. 1. Cardiovascular variables and umbilical artery pulsatility index before, during, and after 5 minutes of norepinephrine infusion in eight fetuses. Values are expressed as percent change of control (group 1).

fetal cardiovascular variables, expressed as percent change from control value.

Norepinephrine infusion caused an increase in mean arterial blood pressure. The increase in arterial pressure was accompanied by a bradycardia that lasted during the first 3 minutes of infusion. Fetal bradycardia had disappeared at 4 and 5 minutes during infusion and 5 minutes after infusion. Umbilical venous pressure significantly increased at 2, 3, and 4 minutes during infusion. Placental perfusion pressure was not significantly elevated during norepinephrine infusion. Umbilical blood flow also did not change. Placental vascular resistance did not change significantly during and after infusion, compared with baseline values. A sufficient number of good-quality umbilical artery blood flow velocity waveforms were obtained for statistical analysis at 1, 4, and 5 minutes of infusion.

After an initial nonsignificant rise in umbilical artery pulsatility index, a tendency toward a decrease was observed during the norepinephrine infusion. The changes, however, were not significant with Bonferroni correction at 1, 4, and 5 minutes of infusion.

After parasympathetic blockade with atropine (group 2). Fig. 2 depicts the results of norepinephrine infusion on the fetal cardiovascular variables after cholinergic blockade by atropine, expressed as percent change from control (Table I). Norepinephrine infusion caused a more pronounced increase in mean arterial pressure, as in the experiments without cholinergic blockade. Fetal heart rate, however, significantly increased during norepinephrine infusion. Umbilical venous pressure increased significantly and returned to baseline values 5 minutes after infusion. Placental perfusion pressure also significantly increased during and after infusion. A significant rise in umbilical blood flow occurred during infusion and was still present at 5 minutes after infusion. Placental vascular resistance did not change during or after infusion. The umbilical artery pulsatility index tended to decrease during the infusion, but the change was not significant. The number of observations of umbilical artery pulsatility index at 1, 2, and 3 minutes of infusion and 5 minutes after infusion were from six, seven, seven, and six fetuses, respectively.

No significant changes in fetal acid-base balance were seen after norepinephrine infusion. Fetal arterial pH was 7.35 ± 0.01 before and 7.31 ± 0.01 after infusion, whereas P_{CO_2} was 5.72 ± 0.30 and 5.73 ± 0.29 kPa, respectively, and P_{O_2} was 1.89 ± 0.25 kPa before and 2.27 ± 0.30 kPa after norepinephrine infusion.

Comment

The purpose of this study was to investigate the effect of fetal hypertension on the umbilical artery flow velocity waveform expressed by the pulsatility index.

Norepinephrine infusion caused arterial hypertension in the fetal circulation, which is in accordance with results of previous studies.[16-19, 23, 24]

The increase in mean arterial pressure had a considerable effect on fetal heart rate in fetuses with the autonomic nervous system intact. Because of baroreflex activity fetal heart rate decreased during the first 3 minutes of infusion but recovered at 4 minutes of infusion. To avoid reflex bradycardia during fetal hypertension, another series of norepinephrine infusions was performed after cholinergic blockade with atropine (group 2), because it is known that bradycardia increases the umbilical artery pulsatility index.[10] A second reason for parasympathetic blockade is the fact that calculation of placental vascular resistance is questionable during bradycardia, because a concomitant decrease in umbilical blood flow during bradycardia cannot be attributed to an increase in vascular resistance.[19, 23] The increase in fetal heart rate in group 2 during norepinephrine infusion is explained by the prevailing β-adrenergic system, because parasympathetic vagal activity is blocked.

Table I. Hemodynamic control variables before norepinephrine infusion in group 1 without atropine and group 2 after atropine administration

Variable	*Control (group 1) (mean ± SE)*	*Control after atropine (group 2) (mean ± SE)*
Umbilical artery pulsatility index	0.99 ± 0.12	0.82 ± 0.14
Fetal heart rate (beats/min)	192 ± 15	222 ± 16
Fetal blood pressure (mm Hg)	43.3 ± 2.9	40.3 ± 4.6
Umbilical venous pressure (mm Hg)	12.4 ± 4.3	15.3 ± 5.6
Fetal blood pressure − Umbilical venous pressure (mm Hg)	30.9 ± 3.6	25.0 ± 2.3
Umbilical blood flow (ml/min)	408 ± 59	335 ± 40
Placental vascular resistance (mm Hg · min · ml^{-1})	0.089 ± 0.019	0.076 ± 0.010

During norepinephrine infusion a tendency of the umbilical artery pulsatility index to decrease was noted in group 1 and in group 2. These changes, however, were not significant after the Bonferroni correction for repeated analyses. In group 1 placental vascular resistance did not change, mainly because of the relatively small increase in perfusion pressure with rather stable umbilical blood flows. In group 2 placental perfusion pressure and umbilical blood flow both increased. Therefore no change in calculated placental vascular resistance occurred. In contrast to the results in group 1, the umbilical arterial-venous pressure difference was more pronounced after cholinergic blockade, and it paralleled the increase in umbilical blood flow and fetal heart rate. The increase in umbilical blood flow in group 2 was very likely related to the increase in fetal heart rate.[23]

Furthermore, norepinephrine infusion caused a significant rise in umbilical venous pressure in both groups. The increase in umbilical venous pressure was more gradual than the increase in arterial pressure, which explains the increase in perfusion pressure during the first 2 minutes of infusion in group 1. The later onset of the umbilical venous pressure increase also was reflected in the higher mean values of calculated pla-

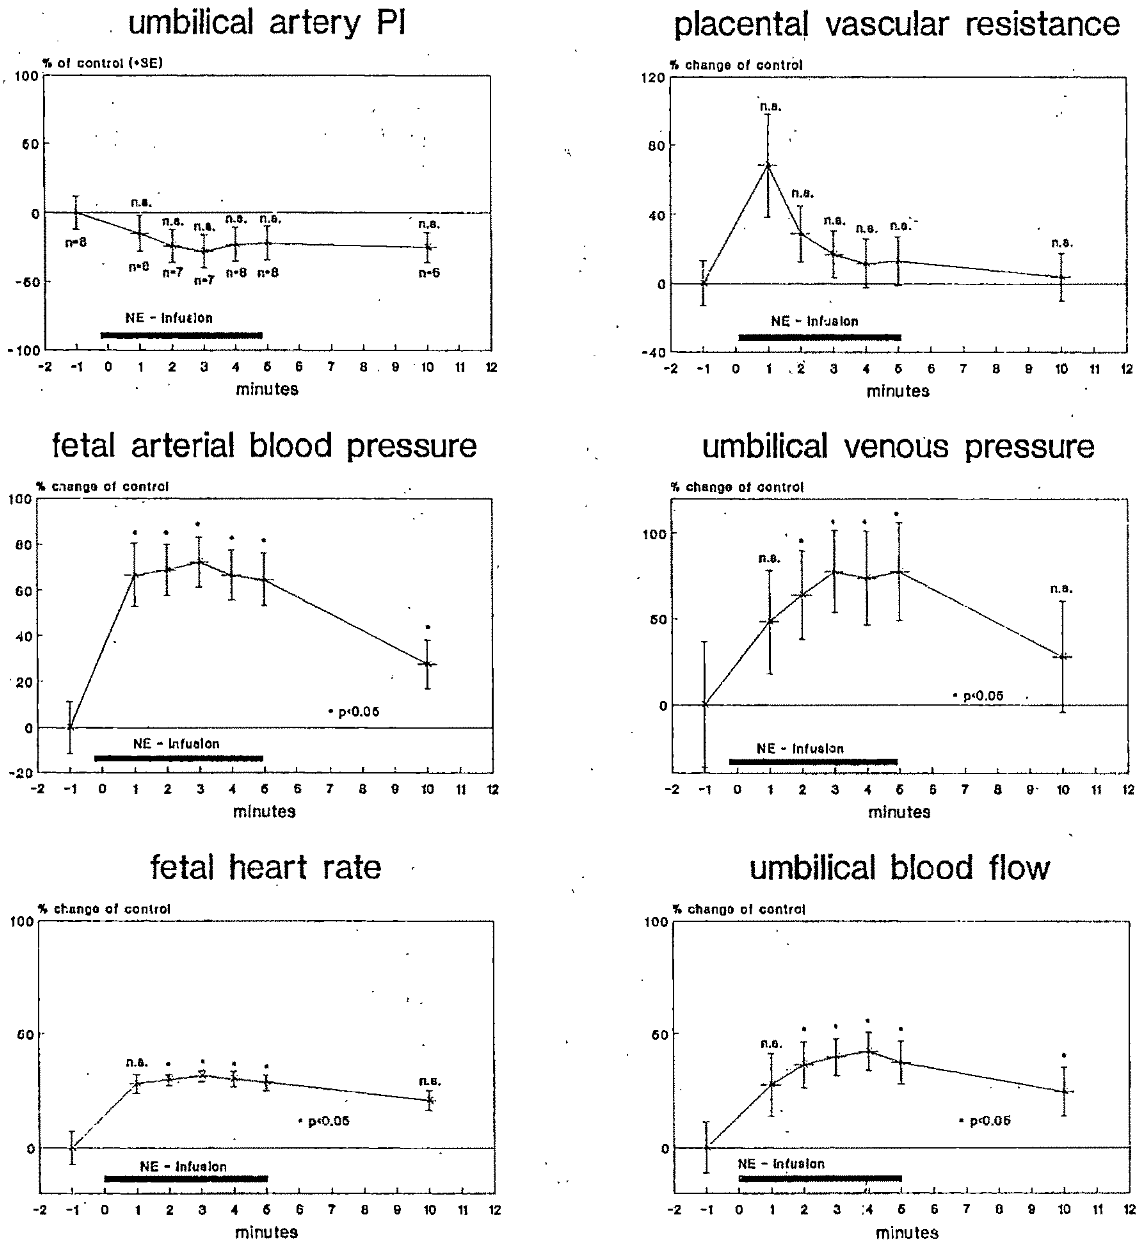

Fig. 2. Cardiovascular variables and umbilical artery pulsatility index after cholinergic blockade by atropine before, during, and after 5 minutes of norepinephrine infusion in eight fetuses. Values are expressed as percent change of control (group 2).

cental vascular resistance during the first 2 minutes of infusion.

Norepinephrine constricts the systemic vascular bed while the umbilical arteries are unaffected. It follows that in cases of catecholamine release, as during hypoxic stress, the fetus is capable of regulation of placental pefusion pressure, not only by increasing arterial blood pressure but also by increasing umbilical venous pressure, to maintain umbilical blood flow and avoid compromise of gas exchange. This is illustrated by the fact that pH, Pco_2 and Po_2 were not affected, which is in accordance with previous reports.[16, 23] We infer that umbilical venous vasomotor tone may play an important role in regulating placental pefusion pressure and umbilical blood flow.

Inferior vena cava pressure is not representative for umbilical venous pressure, since it is only moderately affected by norepinephrine infusion.[24, 25] Placental vascular resistance calculations using vena cava pressure may therefore increase the numerator and hence increase calculated placental vascular resistance.[17, 18] Adamson et al.[24] reported no significant changes in resistance of the umbilical artery and intrinsic cotyledon vasculature during norepinephrine infusion and no change in umbilical blood flow in an acute experiment. They observed, however, a rise in umbilical venous resistance, from which they concluded that the umbilical vein was constricted during norepinephrine infusion. Recently Paulick et al.[26] observed a pressure drop in the umbilical vein, from the placenta to the portal sinus, which increased during hypoxemia, indicating increased resistance. This would distend and recruit vessels in the placenta and hence improve gas exchange.

It is concluded that:

1. Fetal hypertension caused by norepinephrine infusion has no effect on umbilical artery pulsatility index.
2. Norepinephrine infusion does not alter placental vascular resistance.
3. Norepinephrine infusion has no effect on umbilical blood flow.
4. Norepinephrine infusion increases umbilical venous pressure.
5. Norepinephrine infusion does not affect fetal acid-base balance.

We speculate that fetal hypertension has no effect on umbilical artery waveform indices in fetuses with normal placentation and that the fetus is capable of regulating placental perfusion pressure by altering systemic arterial pressure and umbilical venous tone.

Inhibition of oxytocin-induced uterine contractions by an oxytocin antagonist in the pregnant baboon

Laird Wilson, Jr., PhD,[a] Michael T. Parsons, MD,[b] and George Flouret, PhD[c]
Chicago, Illinois, and Tampa, Florida

Uterine contractions were induced with oxytocin in anesthetized pregnant baboons *(Papio anubis)* at three stages of pregnancy (days 140, 156, and 169; normal gestation length, 184 days). After the contractile activity was greater than two to three contractions every 10 minutes, β-mercapto-β, β-cyclopentamethylenepropionic acid^1-[D-Trp^2,Phe^3,Ile^4,Arg^8]-oxytocin, a novel oxytocin antagonist produced in our laboratories, was given simultaneously with the oxytocin for 90 minutes. Contractile force (frequency × mean amplitude) was determined for 30 minutes before and for three 30-minute intervals after the oxytocin antagonist was administered. Animals at 140 days' gestation showed a significant ($p < 0.05$) decrease in contractile force in the first 30-minute interval after oxytocin antagonist infusion was initiated, whereas those at days 156 and 169 showed decreases ($p < 0.05$) at the second 30-minute interval. In addition, in late gestation a higher dose of oxytocin antagonist per unit of oxytocin was required to prevent uterine contractions. In conclusion, these results suggest (1) that an oxytocin antagonist can inhibit oxytocin-induced uterine contractions in the pregnant baboon and (2) that the interval from oxytocin antagonist administration to significant inhibition of uterine contractions appears to increase with advancing gestational age. (AM J OBSTET GYNECOL 1991;165:456-60.)

Key words: Oxytocin antagonist; baboon, pregnant; uterus, contractions; premature labor

Preterm labor and delivery is a major cause of perinatal mortality and morbidity.[1] Potential therapeutic modalities used to delay preterm labor include β-sympathomimetics, magnesium sulfate, calcium blockers, and indomethacin. These treatments can have side effects on the mother or fetus and often are not effective. An oxytocin antagonist has the potential to induce fewer side effects because of the limited number of target tissues for oxytocin. In addition, an oxytocin antagonist would help determine the contribution of endogenous oxytocin to uterine contractile activity during pregnancy and labor.

Recent reports have emphasized the clinical potential of an oxytocin antagonist.[2-6] We have reported the effects of a potent oxytocin antagonist produced in our laboratory that in the rat (1) inhibits uterine contractions induced by exogenous oxytocin in vitro and in vivo, (2) inhibits milk let-down, and (3) disrupts labor.[7] In addition, the oxytocin antagonist inhibited in vitro uterine contractions induced by oxytocin in myometrial tissue obtained at term pregnancy in humans.

The purpose of this study was to demonstrate that the oxytocin antagonist can inhibit uterine contractions induced by oxytocin in the pregnant baboon in vivo and thus establish the potential of the oxytocin antagonist as a tocolytic for preterm labor in humans.

Material and methods

Baboons *(Papio anubis)* with timed pregnancies from the breeding colony of the Biological Resource Laboratory at the University of Illinois were used in these studies. These animals are kept under controlled lighting conditions (12 hours light and 12 hours dark) with lights on at 6 AM and are given food (Purina Primate Chow [Ralston Purina, St. Louis], fruit, and nuts) and water as desired. Normal delivery occurs at 184 ± 2 days (day of mating, day 0). The protocols in this report have been approved by the Animal Care Committee at the University of Illinois.

Five animals each were studied at three stages of pregnancy: days 138 to 142, 153 to 157, and 168 to 172, with the mean for each stage equal to 140, 156, and 169, respectively. Two animals delivered before the third-stage (day 169) study was performed. On the day (8 AM) of a study the animal was sedated with intramuscular injections of ketamine (7.0 mg/kg) and maintained on a regimen of intravenous ketamine drip (10 mg/kg/hr) and intramuscular injections of diazepam (0.5 to 1.0 mg/kg), administered every 30 to 45 min-

utes. The total length of the protocol was 6 to 7 hours. Animals had an initial ultrasonography to locate the placenta and pockets of amniotic fluid for subsequent catheter insertion. A 1 mm outer diameter polyethylene cannula (PE50; Clay Adams, Parsippany, N.J.) was placed transabdominally through an 18-gauge Angiocath catheter (Becton Dickinson Deseret Div., Sandy, Utah) into the amniotic fluid, for monitoring uterine contractions as reflected by intrauterine pressure changes. To induce contractions, oxytocin was infused intravenously beginning at 10 pmol/min (i.e., 5 mU/min) and increasing the rate by 10 pmol/min every 20 to 30 minutes until uterine contractions attained frequencies of two to three every 10 minutes. The oxytocin antagonist, β-mercapto-β,β-cyclopentamethylenepropionic acid^1-[D-Trp^2,Phe^3,Ile^4,Arg^8]-oxytocin (molecular weight, 1145 d), was then infused simultaneously with the oxytocin, beginning with a bolus injection of 3000 nmol and followed by a continuous intravenous infusion of 16 nmol/min oxytocin antagonist until all uterine contractions were suppressed. If uterine contractions remained after oxytocin antagonist treatment was initiated, subsequent bolus injections of oxytocin antagonist (3000 nmol) were given at 30-minute intervals.

Intrauterine pressure changes were monitored by an internal pressure transducer attached to an Epcom (Epcom Medical Systems, Hayward, Calif.) fetal monitor (model 315).

Data were analyzed by calculating the contractile force (Frequency × Mean amplitude) at four 30-minute intervals, one before and three after initiation of the oxytocin antagonist administration. Examination of the data for heterogeneity of variance by Box and Cox transformation analysis was significant; therefore all data underwent square root transformation before analysis. Data were analyzed by repeat analysis of variance with time effect nested within day effect, and, when significant, differences were detected by Duncan's multiple range test.[8] When contractile force was converted to percent of baseline, statistical significance ($p < 0.05$) was determined when the mean plus two times the standard deviation of a given 30-minute interval did not overlap with the mean baseline.

Results

There was no statistical difference ($p < 0.05$) among the maternal body weights (mean ± SEM) of 17.4 ± 0.9, 17.4 ± 0.8, and 18.2 ± 0.7 kg at days 140, 156, and 169 of pregnancy, respectively. The effects of oxytocin and oxytocin antagonist on uterine contractions, expressed as contractile force (Frequency × Mean amplitude) or as a percentage contractile force of the baseline, are illustrated in Fig. 1, *A* and *B*, respectively. An immediate inhibitory effect (first 30-minute interval) of the oxytocin antagonist on contractile force was detected ($p < 0.05$) at day 140 of pregnancy (Fig. 1, *A*), whereas animals at 156 and 169 days of pregnancy have a significant decrease from baseline ($p < 0.05$) at the second 30-minute interval after oxytocin antagonist administration. However, comparisons within the second 30-minute time interval revealed that activity on day 169 was higher ($p < 0.05$) than on days 140 and 156, but by the third 30-minute interval after oxytocin antagonist administration no differences ($p > 0.05$) were detected among the three stages of pregnancy studied. Thus the oxytocin antagonist was very effective in inhibiting uterine contractions induced by oxytocin, but the interval between administration and significant inhibition of uterine con-

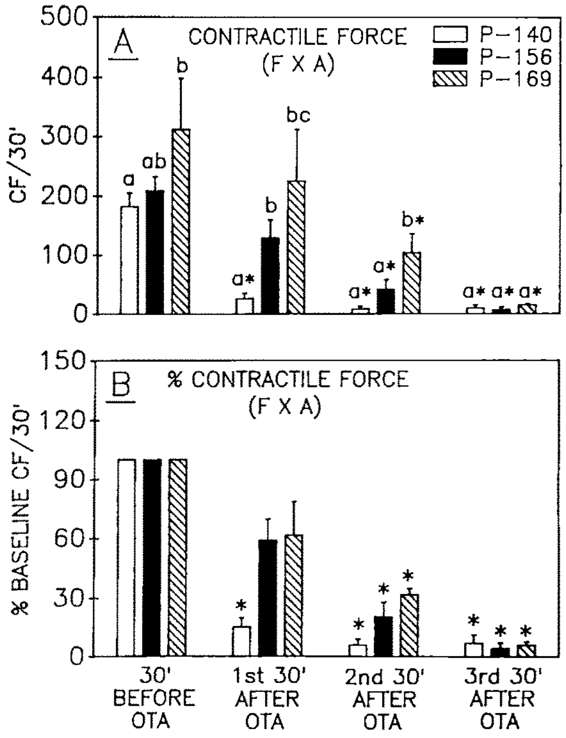

Fig. 1. Depicted are oxytocin-induced uterine contractile force (Frequency × Mean amplitude) (**A**) and percent contractile force *(CF)* of baseline (**B**) in pregnant baboons studied at three stages of pregnancy. Dose of oxytocin infused was incremented until two to three contractions occurred every 10 minutes; it then was infused at this dose for 30 minutes, followed by simultaneous administration of oxytocin antagonist *(OTA)* for 90 minutes. Data were analyzed at four intervals, one 30-minute interval before and three 30-minute intervals after infusion of oxytocin antagonist. Oxytocin antagonist inhibited uterine contractions induced by oxytocin, but the interval from administration of oxytocin antagonist to significant contractile force suppression increased with advancing gestational age. *Bars with different letters* within given 30-minute interval are significantly ($p < 0.05$) different from each other. *Asterisk* indicates differences ($p < 0.05$) from baseline control values ($n = 5$, 5, and 3 for days 140, 156, and 169, respectively; mean ± SEM). **B,** *Asterisk* indicates mean percent contractile force was greater than 2 SD (i.e., $p < 0.05$) from baseline.

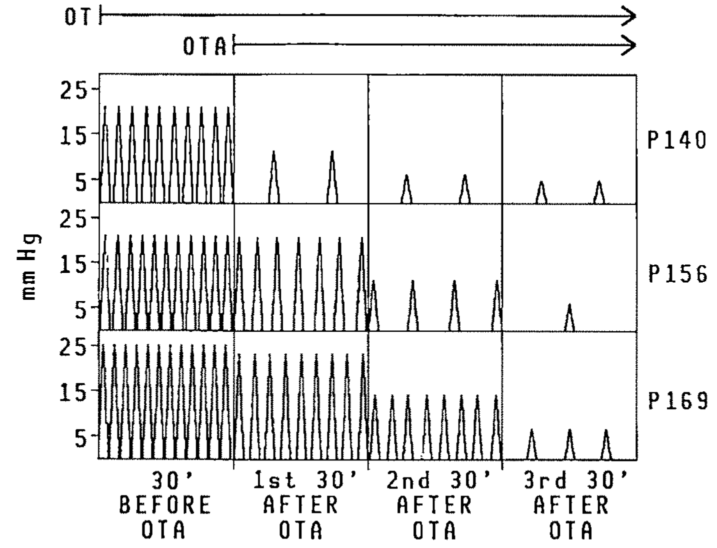

Fig. 2. Diagram showing same data as in Fig. 1 but representing mean frequencies and amplitudes during each 30-minute interval at three stages of pregnancy (days 140, 156, and 169) studied.

tractile force appeared to increase with advancing gestational age. In all instances a significant inhibition of uterine contractile force was noticed within 60 to 90 minutes after the oxytocin antagonist administration. The mean total dose of oxytocin antagonist administered over the 90-minute interval was 5680, 8136, and 7840 nmol for days 140, 156, and 169, respectively. Thus, on average, animals at days 156 and 169 received slightly less than one additional bolus injection of oxytocin antagonist, in addition to the initial bolus injection of 3000 nmol and subsequent oxytocin antagonist infusion. Furthermore, the total amount of oxytocin infused over 90 minutes at days 140, 156, and 169 was 0.405, 0.342, and 0.149 pmol; thus the ratio of oxytocin antagonist to oxytocin infused was about four times greater at day 169 than at day 140. Baseline uterine contractile force (30-minute interval before oxytocin antagonist) was greater on day 169 ($p < 0.05$) than on day 140, even though the trend was for a lower oxytocin infusion rate during this period (mean ± SEM, 45.0 ± 12.6, 38.0 ± 6.6, and 16.6 ± 6.6 pmol oxytocin per minute for days 140, 156, and 169, respectively). This suggests an increased sensitivity of the uterus to oxytocin at this stage of pregnancy (Fig. 1, *A*).

The results of expressing the contractile force as a percentage of the initial baseline are shown in Fig. 1, *B*. Presenting the data as a percentage of initial baseline adjusts for any incipient differences in contractile force and allows for a better appreciation of the relative uterine responses to the oxytocin antagonist at the different stages of pregnancy studied. Between 60 and 90 minutes after the oxytocin antagonist was given, all animals at the three stages of pregnancy studied showed a 95% reduction in contractile force as compared with initial baseline, even though oxytocin was administered continuously.

The frequency and amplitude of contractions are summarized diagrammatically in Fig. 2. The significance of this figure is that it represents the observed mean frequencies and amplitudes for each 30-minute interval and provides a visual comparison for the relative changes in activity of these two parameters.

Comment

This study demonstrates that the oxytocin antagonist, β-mercapto-β,β-cyclopentamethylenepropionic acid^1-[D-Trp^2,Phe^3,Ile^4,Arg^8]-oxytocin, produced in our laboratory inhibits uterine contractions induced by exogenous oxytocin in the pregnant baboon in vivo and that the interval from administration of the oxytocin antagonist to the time of significant inhibition of uterine contractile force appears to increase with advancing gestational age. These results suggest that the oxytocin antagonist has the potential of inhibiting preterm labor in humans, assuming endogenous oxytocin has a significant role in this process. Although the latter point has been controversial,[9-11] recent observations in our laboratory indicate that the oxytocin antagonist can disrupt labor in pregnant rats[7] and inhibit both spontaneous nocturnal and labor contractions in pregnant baboons,[12] thus adding support to this concept.[13] Similarly, Hahn et al.[3] have reported in pregnant rats a delay in delivery time of pups with the use of an oxytocin antagonist that is different from the one described here. In addition, the reports of Akerlund et al.[2] and Andersen et al.,[6] that a structurally different oxytocin antagonist administered to humans can stop preterm labor contractions, suggest that the oxytocin antagonist described in the present study has a similar potential.

We have concluded that the oxytocin antagonist is more effective in early than late stages of the last third of pregnancy on the basis of the observation that the interval required for the oxytocin antagonist to suppress uterine contractions increases with advancing gestational age. These results are even more impressive if one considers that the total dose of oxytocin antagonist administered in this study was greater at days 156 and 169 than at day 140, and yet the rapidity of effectiveness of the oxytocin antagonist was diminished at these later stages of pregnancy. These data correlate with the observation in our laboratory that the oxytocin antagonist is more effective in suppressing uterine contractions induced by exogenous oxytocin in an in vitro oxytocic bioassay in tissue obtained from day 15 of pregnancy in the rat compared with delivery (unpublished observations). An explanation for the decrease in effectiveness of the oxytocin antagonist with advancing gestational age is only speculative. It seems not to be a function of altered oxytocin antagonist metabolism or half-life, because it occurs in vitro with rat uterine tissue. However, an effect on oxytocin metabolism in vivo cannot be totally eliminated. Uterine oxytocin receptor number increases dramatically at the end of pregnancy in a number of species.[13-15] It is likely that our results are related to the probability of oxytocin and oxytocin antagonist interacting with the oxytocin receptor or to changes in postreceptor amplification of the signal. Finally, it is possible that decreased effectiveness of the oxytocin antagonist with advancing gestation is simply related to the higher contractile force baseline. However, this explanation seems unlikely for several reasons. First, and most relevant, is Fig. 1, *B*. The expression of the contractile force as a percentage of the baseline corrects for any initial baseline differences. The delayed effect of the oxytocin antagonist with advancing gestation is apparent even when this correction is made. Second , the baseline contractile force at day 156 did not differ ($p > 0.05$) from that at day 140, yet there was a statistically significant delay in oxytocin antagonist action at this stage of pregnancy. Further studies will be required to provide a definitive explanation.

The observation that the uterus appears to be more sensitive to oxytocin at day 169 than at day 140 is most likely related to an increase in oxytocin receptor number between days 140 and 169. Uterine oxytocin receptor number has been reported to increase with advancing gestational age in other species such as the rat and human,[13-15] and this likely occurs in the baboon uterus as well.

The effectiveness of the oxytocin antagonist in inhibiting uterine contractions in this study are very impressive, considering that the response was achieved while exogenous oxytocin was continuously infused. In normal pregnancies the release of endogenous oxytocin is pulsatile and responds reflexively (Ferguson reflex) to the positive feedback effects of uterine contractions and cervical stretching.[16,17] Thus one might expect the oxytocin antagonist to be more effective in blocking spontaneous uterine contractions induced by endogenous oxytocin, because the endogenous release of oxytocin is most likely decreased as the uterine contractions diminish. Therefore the oxytocin antagonist dosage and the length of administration required in this study are probably greater than those necessary to inhibit spontaneous uterine contractions induced by endogenous oxytocin. This assumption is supported by the observation by our laboratory that only a single bolus injection of 3000 nmol of oxytocin antagonist is required to inhibit both spontaneous nocturnal and labor uterine contractions in the pregnant baboon.[12]

Finally, although this part of the study is not shown, after the oxytocin antagonist infusion was stopped, the oxytocin infusion was continued, often at much higher levels (e.g., 60 pmol/min), to determine if uterine contractions might be reestablished. Uterine contractions usually began within 15 to 20 minutes, although not at the level of uterine activity detected before the oxytocin antagonist was administered. Time limitations prevented an adequate assessment of this observation. However, in a tethered baboon model developed in our laboratory, where spontaneous uterine contractions of labor were suppressed with several large doses of the oxytocin antagonist, infusion of oxytocin 1 hour after the termination of the oxytocin antagonist administration prompted immediate uterine contractions that ultimately resulted in labor 3½ hours later.[12] Therefore it seems likely that after uterine contractions are suppressed with the oxytocin antagonist, this effect can be reversed with oxytocin within 1 hour, if not less. In addition, if necessary, prostaglandin F_{2a} or E_2 can be administered because each can induce uterine contractions in the presence of the oxytocin antagonist in the rat[7] and the pregnant baboon (unpublished observations).

In conclusion, a potent oxytocin antagonist has been developed in our laboratory that inhibits in vivo uterine contractions induced by exogenous oxytocin in the pregnant baboon. The interval required for inhibition of uterine contractions appears to increase with advancing gestational age, but the oxytocin antagonist ultimately inhibited uterine contractions in all studies within 60 minutes after the initiation of oxytocin antagonist administration. The results of these and other studies suggest that the oxytocin antagonist has the potential of inhibiting labor, and probably preterm labor, contractions in humans.

We thank Joanne McNeal and Denis Almahdi for helping with the baboon surgery and Irma Lopez and Angela Surman for assistance in the manuscript preparation. Also we acknowledge the Scientific Computer Workstation and the Biostatistics Facility of the Research Resources Center, University of Illinois at Chicago, which provided the equipment and assistance necessary to conduct these computations.

The prevalence of recurrent spontaneous abortions, cancer, and congenital anomalies in the families of couples with recurrent spontaneous abortions or gestational trophoblastic tumors

Hong-Nerng Ho, MD, Thomas J. Gill III, MD, Chang-Yao Hsieh, MD, Yu-Shih Yang, MD, and Tzu-Yao Lee, MD

Taipei, Taiwan, and Pittsburgh, Pennsylvania

This study extends our previous work on the genetics of recurrent spontaneous abortion and of gestational trophoblastic tumors in an ethnically homogeneous population of Chinese in Taiwan by comparing the prevalence of recurrent spontaneous abortions, cancer, and congenital anomalies in the first-, second-, and third-degree relatives of the index couples to that of normally fertile couples from the same population. The rationale for this study was to provide another test for our hypothesis that genes linked to the major histocompatibility complex are responsible for the diseases in the index couples. If they are, these genes should segregate with a higher frequency in the relatives of the index couples than in the relatives of normally fertile couples and lead to a higher prevalence of these diseases in the extended families. Such a difference was found and adds support to our hypothesis that major histocompatibility complex–linked genes affect growth, development, and susceptibility to cancer. (AM J OBSTET GYNECOL 1991;165:461-6.)

Key words: Genetics of reproduction, genetics of cancer, human leukocyte antigen sharing, recurrent spontaneous abortion, congenital anomalies

Experimental studies in rats and observations in the clinical literature led us to develop the hypothesis that recessive genes linked to the major histocompatibility complex influence growth, development, reproduction, and susceptibility to cancer.[1-5] We tested this hypothesis in a series of clinical studies in an ethnically homogeneous Chinese population in Taiwan (originally emigrated from the southeastern part of mainland China) to minimize the genetic variation in the population. The basic assumptions of the studies were that sharing of major histocompatibility complex antigens [human leukocyte antigens (HLA) in human beings] indicates the sharing of the major histocompatibility complex–linked region as well and that this region contains recessive genes that affect the growth and reproductive processes. We examined couples for HLA antigen sharing and the prevelance of gestational trophoblastic tumors and of recurrent spontaneous abortions and compared the results with those in normally fertile couples from the same population.

Couples in whom the woman had a gestational trophoblastic tumor[6] and couples with primary or secondary recurrent spontaneous abortions[7] shared HLA antigens more frequently than did normally fertile couples. No specific HLA antigen was uniquely shared, and the strongest correlation was sharing of three or more of the HLA-A, B, DR, and DQ antigens. This observation strengthens our hypothesis that the HLA genes themselves are only passenger genes and that the genes responsible for these defects are on the same segment of chromosome 6 and linked to the genes encoding the HLA antigens. Two collateral observations are consistent with this genetic interpretation. First, gestational trophoblastic tumors have a high prevalance in the Taiwan Chinese population and a very low prevalence in whites, and the genetic association was observed only in the Chinese population in Taiwan: thus the disease is genetically determined (familial) in Taiwan Chinese and sporadic in whites. Retinoblastoma also has familial and sporadic forms.[8, 9] Second, immunotherapy for recurrent spontaneous abortion was not effective in this Taiwanese population, as would be expected for a genetically determined disease.[10]

This study extends our work in this Taiwan Chinese population to examine the prevalence of recurrent spontaneous abortions, cancer, and congenital anomalies in the first-, second- and third-degree relatives of the index couples (i.e., those couples with gestational trophoblastic tumors or recurrent spontaneous abortions in our previous studies).[6, 7] The rationale for this

approach to test our hypothesis was that the major histocompatibility complex–linked genes responsible for the diseases in the index couples should segregate with a higher frequency in their relatives than in the relatives of the normally fertile couples and lead to a higher prevelance of recurrent spontaneous abortions, cancer, and congenital anomalies in the relatives of the index couples. Such a relationship was found and, coupled with our previous studies,[6,7] adds further support to our hypothesis that major histocompatibility complex–linked genes affect growth, development, and susceptibility to cancer. These major histocompatibility complex–linked genes may be related to tumor suppressor genes,[8,9] and such genes may play a broad role

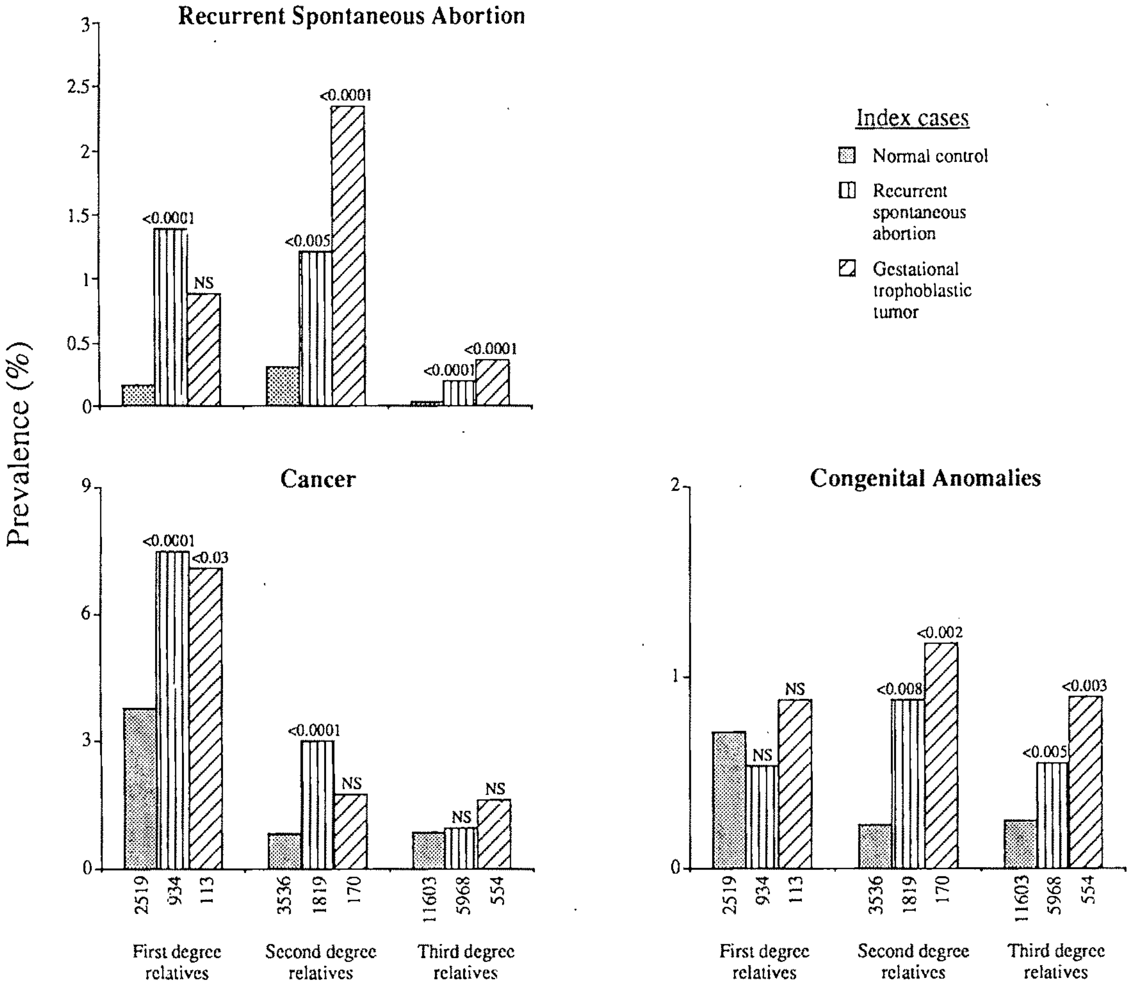

Fig. 1. Prevalence of recurrent spontaneous abortion, cancer, and congenital anomalies in the first-, second-, and third-degree relatives of couples who were normally fertile, who experienced recurrent spontaneous abortions, or in whom a gestational trophoblastic tumor developed in the woman.

in the control of growth and not be confined only to a role in oncogenesis.

Material and methods

The couples whose families were examined (index couples) were those who had previously been studied for gestational trophoblastic tumors, recurrent spontaneous abortions, and the effects of immunotherapy. They were all patients from the Obstetrics Clinic of the National Taiwan University Hospital, and they have been described in detail.[6, 7, 10]

The first-, second- and third-degree relatives of both the husband and the wife in the index couples and in the normally fertile controls were carefully interviewed by two nurses who were well trained in interviewing techniques and who were unaware of the purpose of the interview. The interview focused on a complete reproductive history, with special emphasis on recurrent (at least three) spontaneous abortions, and on the presence and nature of cancer and of congenital anomalies in any living or dead relative. The data on cancer were collected as the total prevalence and as the prevalence in persons younger than 40 years old exclusive of childhood cancers such as leukemia (childhood data would not be reliable in this population). After the interview, a questionnaire covering the same information was sent to those interviewed to cross-check the information. If there was any discrepancy, a second interview was scheduled to reconcile the differences.

The data from the families of the index couples were compared with those of the families of normally fertile couples with the use of a 2×2 contingency test; $p \leq 0.05$ was the level of significance.

Results

The prevalence rates of recurrent spontaneous abortions, cancer, and congenital anomalies for the first-degree relatives of the index and control couples are

given in Table I; data for the second- and third-degree relatives are in Table II. The data are summarized graphically in Fig. 1; for recurrent spontaneous abortions, only the total prevalence is shown. When either couples with recurrent spontaneous abortions or couples in whom a gestational trophoblastic tumor developed in the woman are taken as the index cases, there is a higher prevalence of recurrent spontaneous abortions, cancer, and congenital anomalies in the first-, second-, and third-degree relatives. The only significant exceptions to this generalization are the lack of cancer in the third-degree relatives and the lack of congenital anomalies in the first-degree relatives. There is no clear reason why the correlation with cancer should

be lost in the third-degree relatives unless some of the genes involved in the susceptibility to cancer were lost in the more distant relatives. Such diffusion of genes in a population has been described by Cavalli-Sforza and Bodmer.[11] The number of first-degree relatives examined may be too small as compared with the prevalence of congenital anomalies in the population to show a significant deviation from the population mean. This explanation appears reasonable because of the significant increase in congenital anomalies in the second- and third-degree relatives for whom the numbers examined are greater.

The distribution of cancers (Table III) and of congenital anomalies (Table IV) in the first-, second-, and third-degree relatives of the normally fertile controls and of the index cases is quite broad and does not show a pattern unique to any one group. The relatively high prevalence of hepatoma in all groups reflects the high prevalence of this disease in the Taiwan Chinese population.[12, 13]

Comment

The evidence of the increase in recurrent spontaneous abortions, cancer, and congenital anomalies in the first-, second-, and third-degree relatives of couples with recurrent spontaneous abortions or of couples in whom a gestational trophoblastic tumor developed in the woman provides epidemiologic support for our hypothesis that major histocompatibility complex–linked genes are involved in the pathogenesis of these diseases. The data from this and other clinical studies[6, 7] and from experimental studies[4, 5, 14] provide strong enough support for this hypothesis to warrant studies at the molecular level to identify the major histocompatibility complex–linked genes involved.

An interesting speculation may be made on the basis of the clinical data presented here and of experimental evidence in rats. Studies in rats have shown that there are at least two separate major histocompatibility complex–linked genes or groups of closely linked genes that affect growth and reproduction: *dw-3*, which affects body size, and *ft*, which affects fertility.[14] Loss of these genes leads to growth defects, partial loss (25% to 30%) of homozygous offspring, and increased susceptibility to chemical carcinogens.[15] Possibly the phenotypes of primary or secondary recurrent spontaneous abortion, increased susceptibility to cancer, and congenital anomalies are a result of losses of different constellations of similar genes in human beings. The severity of a particular defect, measured roughly by the length of survival of the person carrying it, may reflect the number of these genes lost: embryonic death more than primary recurrent spontaneous abortion more than secondary recurrent spontaneous abortion more than susceptibility to cancer. Whereas this explanation may eventually prove to be too simple, it provides one framework within which to examine the genetics of growth and reproduction, and it is consistent with the concept of tumor suppressor genes and the increased susceptibility to cancer after their loss.[8, 9]

The mechanism responsible for diminished neutrophil production in neonates delivered of women with pregnancy-induced hypertension

Joyce M. Koenig, MD,[a] and Robert D. Christensen, MD[b]
Salt Lake City, Utah

The neonatal neutropenia after pregnancy-induced hypertension is a function of diminished neutrophil production. These studies test the hypothesis that this diminution is due to decreased production of neutrophilic growth factors, reduced responsiveness of neutrophil progenitors to these factors, or the presence of an inhibitor. While the concentrations of placentally derived colony-stimulating factors were similar in normotensive and hypertensive gestations, bioassay demonstrated less colony-stimulating activity in placental conditioned media from hypertensive gestations. Evaluation of the responsiveness of progenitors to recombinant factors revealed no differences between those from normotensive and hypertensive gestations. However, neutrophilic colony formation in vitro was significantly inhibited after the addition of conditioned media or sera from hypertensive gestations, whereas the addition of these from normotensive gestations had no inhibitory effect. Thus this common maternal-fetal disorder is associated with an inhibitor of neutrophil production, which is elaborated by the placenta and present in cord blood serum. (AM J OBSTET GYNECOL 1991;165:467-73.)

Key words: Neonate, neutrophil, pregnancy-induced hypertension, inhibitor

Neutropenia is frequently observed in neonates delivered of women with pregnancy-induced hypertension.[1-3] Studies by Manroe et al.,[1] Brazy et al.,[2] Engle and Rosenfeld,[3] and our group[4] indicate that neutropenia is present in 40% to 50% of such neonates and in up to 80% of neonates when maternal hypertension is severe (diastolic blood pressure ≥110 mm Hg). Although neutropenia is usually transient, these neonates may be at greater risk for nosocomial infection in the first weeks of life.[4]

Our previous investigations have established that the neonatal neutropenia associated with pregnancy-induced hypertension is the kinetic result of diminished neutrophil production.[4] We postulated that determination of the mechanism resulting in this diminished production might facilitate our management of this neutropenia and further our understanding of this common maternal-fetal disorder. These studies were performed to test the hypothesis that the cause of the reduced neutrophil production might be one of the following: (1) diminished production of the neutrophilic growth factors, granulocyte colony-stimulating factor, or granulocyte-macrophage colony-stimulating factor; (2) reduced responsiveness of neutrophil progenitor cells to granulocyte or granulocyte-macrophage colony-stimulating factors; or (3) elaboration of an inhibitor of fetal neutrophil production.

Material and methods

Subjects. Study subjects included six neonates (range, 28 to 34 weeks) delivered of mothers with severe pregnancy-induced hypertension (diastolic pressure ≥110 mm Hg on two readings ≥6 hours apart[5]) and seven gestational age–matched neonates (range, 24 to 37 weeks) delivered after normotensive, uncomplicated gestations. None of the neonates delivered of hypertensive women were neutropenic for >30 hours.

To provide target cells for the clonogenic assays, normal hematopoietic progenitor cells were obtained from marrow aspirates of seven healthy adult volunteers. All studies were performed according to a protocol approved by the University of Utah Institutional Review Board.

Serum concentrations and placental production of granulocyte and granulocyte-macrophage colony-stimulating factors. For the serum studies, cord blood was aseptically obtained immediately after delivery, and the resulting serum was stored at −70° C until assay.

Serum concentrations of immunoreactive granulocyte and granulocyte-macrophage colony-stimulating factors were determined by enzyme-linked immunosorbent assay (ELISA, G-CSF, AmGen Laboratories, Thousand Oaks, Calif.; GM-CSF, Genzyme Corp., Boston). Colony-stimulating factor biologic activity in the serum was assessed by coculturing serum (or α-minimum essential medium, HyClone Laboratories, Logan, Utah, as a control) with normal hematopoietic progenitor cells in the absence of recombinant growth factors. As a positive control, recombinant granulocyte and granulocyte-macrophage colony-stimulating factors (Immunex Corporation, Seattle) were added to one set of cultures.

In other studies we evaluated production of these factors by placental tissue. Placentas were obtained immediately after delivery from hypertensive or normotensive gestations. With a sterile technique, the overlying membranes were stripped, and tissue from the fetal side of each placenta was minced and serially rinsed in α-minimum essential medium. Three pieces, with a total weight of 0.15 gm, were placed into 35 mm culture dishes (Becton Dickinson Labware, Oxnard, Calif.) containing 3 ml of α-minimum essential medium with 1% Nutradoma NS (Boehringer-Mannheim Corp., Indianapolis). Plates were then incubated at 37° C in a humidified 5% carbon dioxide–air mixture and supernatants were harvested after 48 hours. After centrifugation at 2000 *g* for 10 minutes, supernatants were filtered through a 0.22 μm filter (Millipore Products Division, Bedford, Mass.), and the filtrate was stored at −70° C until assay. Immunoreactive levels of the factors were determined in the placental conditioned media with an enzyme-linked immunosorbent assay, and colony-stimulating factor biologic activity was determined with our clonogenic assay, noted above.

Responsiveness of neutrophil progenitors to recombinant granulocyte and granulocyte-macrophage colony-stimulating factors. Samples of umbilical cord blood were obtained from the placental vein immediately after delivery and anticoagulated with 10 to 30 units of preservative-free heparin (Squibb-Marsam, Inc., Cherry Hill, N.J.) per milliliter of blood. After Ficoll-Hypaque (Pharmacia Inc., Piscataway, N.J.) centrifugation and one wash in α-minimum essential medium, the light-density (specific gravity, <1.077) mononuclear cells were depleted of T-lymphocytes and macrophages by means of plastic adherence and negative panning techniques, as previously described.[6] Cultures of neutrophil progenitor cells were performed with a modification[7] of the method of Iscove et al.[8] Cultures were plated in quadruplicate at cell concentrations of 0.05 to 0.20 × 10^6 cells per milliliter. After 10 days' incubation, granulocyte-macrophage colonies were enumerated in situ with an inverted stereomicroscope. In the studies that assessed sensitivity of fetal neutrophil progenitor cells to recombinant growth factors, either granulocyte or granulocyte-macrophage colony-stimulating factors were added to cultures at various concentrations (0.001, 0.01, 0.1, 1.0, or 2.0 ng/ml). In other studies recombinant factors (granulocyte and granulocyte-macrophage colony-stimulating factors, interleukin-3, and macrophage colony-stimulating factor [Immunex]) were added at a concentration of 1 ng/ml to the culture medium.

Experiments to detect inhibitors of neutrophil production. Bone marrow progenitor cells from healthy adult volunteers were cultured in the presence of maximally stimulatory (plateau) concentrations (1 ng/ml each) of several recombinant factors (granulocyte, macrophage, and granulocyte-macrophage colony-stimulating factors; interleukin-3). To these cultures was added cord blood serum from normotensive or hypertensive gestations (5% or 15% concentrations) or placental conditioned media from normotensive or hypertensive gestations (5% or 10% concentrations).

Erythropoietin concentrations in cord blood serum and in placental conditioned media were measured with an enzyme-linked immunosorbent assay (AmGen).

Statistical analysis. Statistical analysis was accomplished by either Student's *t* test, Mann-Whitney U test, or the Student–Newman-Keuls test for multiple comparisons, as applicable.

Results

Placental production and serum concentrations of granulocyte and granulocyte-macrophage colony-stimulating factors. The first studies examined placental elaboration and cord blood concentrations of granulocyte and granulocyte-macrophage colony-stimulating factors from both normotensive and hypertensive gestations. Elaboration of these factors from placentas of normotensive and hypertensive gestations did not differ, as determined by measuring immunoreactive concentrations in placental conditioned media (granulocyte colony-stimulating factor: 440 ± 210 pg/ml in normotensive gestations vs 480 ± 150 pg/ml in pregnancy-induced hypertension; granulocyte-macrophage colony-stimulating factor: 7 ± 4 pg/ml in normotensive gestations vs 12 ± 1 pg/ml in pregnancy-induced hypertension). However, bioassay demonstrated significantly less biologically active colony-stimulating factor in the conditioned media from hypertensive gestations (Fig. 1).

Immunoreactive granulocyte and granulocyte-macrophage colony-stimulating factor concentrations in cord blood from normotensive and hypertensive gestations were immeasurably low (≤5 pg/ml). Colony-stimulating factor bioassay revealed significantly less colony-stimulating factor in serum from hypertensive

gestations (7 ± 4 colonies per 10^6 plated cells vs 44 ± 17 colonies per 10^6 plated cells in normotensive gestations, $p < 0.05$). In addition, sera from both groups yielded fewer granulocyte-macrophage colonies than when the cultures were stimulated with 1 ng/ml each of granulocyte and granulocyte-macrophage colony-stimulating factor (4497 ± 75 colonies per 10^6 plated cells, $p < 0.001$).

Responsiveness of neutrophil progenitors to recombinant granulocyte and granulocyte-macrophage colony-stimulating factor. We first examined cord blood concentrations of neutrophil progenitor cells (±SEM) after hypertensive and normotensive gestations when stimulated with plateau concentrations of granulocyte (2 ng/ml) or granulocyte-macrophage colony-stimulating factor (1 ng/ml). As shown in Table I, relatively few neutrophil progenitor cells were detected in cord blood after hypertensive gestations. We next evaluated the in vitro sensitivity of fetal neutrophil progenitor cells from hypertensive and normotensive gestations to recombinant granulocyte and granulocyte-macrophage colony-stimulating factor (Fig. 2). As shown in the figure, there were no differences observed between the normotensive (control) and hypertensive (pregnancy-induced hypertension) gestations with respect to the responsiveness of their progenitors to granulocyte (upper panel) or granulocyte-macrophage colony-stimulating factor (lower panel).

Experiments to detect inhibitors of neutrophil production. We evaluated placental conditioned media and cord blood for the presence of an inhibitor of neutrophil production. As shown in Fig. 3, granulocyte-macrophage colony growth in the presence of recombinant factors alone (control group) was similar to that observed when the recombinant factors were combined with placental conditioned media from normotensive gestations. However, granulocyte-macrophage colony growth was significantly inhibited when placental con-

ditioned media from hypertensive gestations were added to the cultures. Further inhibition was noted when the concentration of the placental conditioned media was increased to 10%. In other studies sera from neonates delivered of normotensive or hypertensive women were added to cultures containing recombinant factors (Fig. 4). As with the placental conditioned media studies, granulocyte-macrophage colony growth was similar in cultures stimulated with the recombinant factors alone or in the presence of sera from normotensive gestations. Again, however, clonogenesis was significantly inhibited by sera from the hypertensive gestations.

Erythropoietin concentrations in the cord blood of neonates delivered of women with severe pregnancy-induced hypertension were significantly higher than in neonates with Rh isoimmunization, normal term infants, and otherwise healthy preterm neonates (Fig. 5). However, erythropoietin concentrations in the placental conditioned media of hypertensive and normotensive groups were similar (10.0 ± 0.2 vs 10.7 ± 0.3 mU/ml).

Comment

Neutropenia occurs in nearly half of all neonates delivered of women with pregnancy-induced hypertension.[1-4] Since hypertension complicates 5% to 6% of all pregnancies,[5] this variety of neutropenia occurs in 2% to 3% of all births, and therefore is the most common neutropenia during the first days of life. In previous studies we observed that the neonatal neutropenia associated with pregnancy-induced hypertension is the kinetic result of reduced fetal production of neutrophils.[4]

Neutrophil production occurs by clonal maturation of progenitor cells under the regulatory control of a family of glycoproteins known as hematopoietic growth factors.[9] Although the actions of several such factors appear to be required for neutrophil production in vitro,[9] studies in animals[10] and humans[11] indicate that granulocyte and granulocyte-macrophage colony-stimulating factors are particularly important. However, whereas interleukins IL-6 and IL-3 appear to act on primitive progenitors, synergism with the more lineage-specific granulocyte and granulocyte-macrophage colony-stimulating factors does occur.[9]

We hypothesized that the reduced neutrophil production might be the result of one, or a combination, of the following: (1) diminished production of granulocyte or granulocyte-macrophage colony-stimulating factors, (2) reduced responsiveness of neutrophil progenitor cells to granulocyte or granulocyte-macrophage colony-stimulating factors, or (3) elaboration of an inhibitor of neutrophil production. These studies were undertaken to examine each of these possibilities, so that additional investigations could concentrate on the most likely prospects.

In this study we did not observe any differences in elaboration of granulocyte and granulocyte-macrophage colony-stimulating factors by placental tissue obtained from hypertensive versus normotensive gestations. Studies by Burgess et al.,[12] Azoulay et al.,[13] and Bartocci et al.[14] illustrate the importance of the placenta in the generation of hematopoietic regulatory factors. It is clear that other tissues contribute an equal or greater role in their production. For example, endothelial cells,[15] fibroblasts,[16] macrophages,[17] and T lymphocytes[18] all display the capacity to elaborate granulocyte and granulocyte-macrophage colony-stimulating factors messenger ribonucleic acid transcripts and active granulocyte and granulocyte-macrophage colony-stimulating factors glycoproteins. Indeed, to conclude that the hyporegenerative neutropenia in neonates delivered of women with pregnancy-induced hypertension is the result of reduced fetal production of the neutrophilic growth factors, examination of production rates by all of these cell types in vivo would be required. Thus confirmation of our speculation that production of granulocyte and granulocyte-macrophage colony-stimulating factors is normal in these fetuses awaits further study. Similarly, although we have identified an in vitro inhibitor of neutrophil production elaborated by the placenta and present in cord blood in hypertensive gestations, we have not established conclusively its role as an inhibitor in vivo. In addition, diminished concentrations of unmeasured growth factors that are synergistic with granulocyte and granulocyte-macrophage colony-stimulating factors could also account for a reduction in biologic activity. In spite of these limitations, the consistencies in our

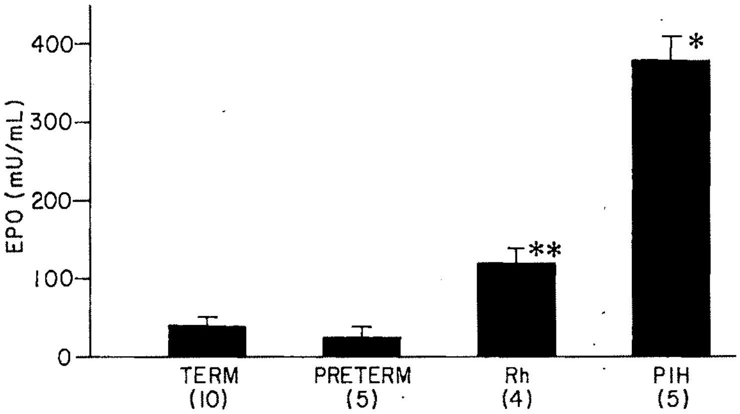

Fig. 5. Umbilical venous serum erythropoietin *(EPO)* concentrations. Numbers in parentheses are number of subjects. experimental results justify our speculation that the hyporegenerative neutropenia might be due to elaboration of an inhibitor of neutrophil production. None of the subjects in this study had the less common prolonged (>60 hours' duration) variety of neutropenia.[4] The mechanism that results in prolonged neutropenia and how this might differ from our observations would be an important topic for future investigation.

High concentrations of erythropoietin inhibit neutrophil production from progenitors in vitro,[19] and a growing body of evidence suggests that high erythropoietin concentrations also might inhibit fetal production of neutrophils in vivo. Specifically, neutrophil production is reduced in newborn rats injected with high concentrations of erythropoietin,[20] human fetuses exposed to high concentrations in utero generally have a hyporegenerative neutropenia during the first days of life,[21] and anemic neonates treated with recombinant erythropoietin can have neutropenia.[22] Because of these actions of erythropoietin on neutrophil production, we speculated that it might indeed be the inhibitor of neutrophil production elaborated by placental cells and present in the cord blood of fetuses delivered to women with pregnancy-induced hypertension. Placental production of erythropoietin is reasonable, because macrophages, rather than cells in the renal interstitium, appear to be the major source in utero,[23] and placental tissue is abundant with macrophages.[24, 25] In support of this speculation, we observed concentrations of erythropoietin in the blood of neonates delivered of women with pregnancy-induced hypertension that were higher than those measured in neonates with Rh-hemolytic disease. However, erythropoietin concentrations were not greater in supernatants of cultured placental cells from hypertensive versus normotensive gestations. Additionally, erythropoietin concentrations were lower than those known to inhibit neutrophil production in vitro.[19] Thus we conclude that erythropoietin is not a likely candidate as the inhibitor of neutrophil production elaborated by placental tissue in pregnancy-induced hypertension.

In summary, the neonatal neutropenia accompanying maternal pregnancy-induced hypertension does not appear to be a function of either reduced placental elaboration of granulocyte and granulocyte-macrophage colony-stimulating factors or a diminished responsiveness of neutrophil progenitors to these factors. However, an inhibitor of neutrophil production is present in cord blood serum and elaborated by the placenta in pregnancy-induced hypertension. We speculate that the identification of this inhibitor may further our understanding of this common maternal disorder and its effects on the fetus.

Hemorrhage-induced reductions in plasma atrial natriuretic factor in the ovine fetus

Cecilia Y. Cheung, PhD, and Robert A. Brace, PhD
La Jolla, California

To investigate the effects of blood volume reduction on fetal plasma atrial natriuretic factor concentrations, chronically catheterized ovine fetuses at 109 to 138 days' gestation were subjected either to withdrawal of two consecutive blood samples or to a moderate hemorrhage. In fetuses from which two blood samples of 3.5 ml each (approximately 1% of fetal blood volume) were withdrawn under basal conditions at 15- to 30-minute intervals, plasma atrial natriuretic factor concentrations in the second sample decreased by 17 ± 7 pg/ml from 178 ± 8 pg/ml in the first sample ($p < 0.02$). If the fetal blood removed during the first sample was replaced with an equal volume of maternal blood, plasma atrial natriuretic factor concentrations did not change significantly. In these same samples, plasma arginine vasopressin and angiotensin II concentrations were unchanged between the two samples regardless of whether volume was replaced. In fetuses subjected to hemorrhages of 21% ± 2% over 10 minutes without blood replacement, plasma atrial natriuretic factor concentration at 1.5 hours after hemorrhage was suppressed by 42 ± 10 pg/ml from basal level of 139 ± 9 pg/ml ($p < 0.05$). Plasma atrial natriuretic factor returned to control levels by 5.5 hours after hemorrhage as blood volume returned to normal. Thus in the ovine fetus a reduction in blood volume results in a decrease in plasma atrial natriuretic factor concentrations. Also, atrial natriuretic factor appears to be more sensitive to changes in blood volume than other vasoactive hormones studied. (AM J OBSTET GYNECOL 1991;165:474-81.)

Key words: Blood volume, fetal sheep, atrial natriuretic factor, arginine vasopressin, angiotensin II

Atrial natriuretic factor is present in high concentrations in the fetal circulatory system.[1-3] Intravascular administration of exogenous atrial natriuretic factor significantly affects the fetal cardiovascular system in much the same way it affects the adult cardiovascular system.[4, 5] Recent studies have explored the regulation of atrial natriuretic factor release in the fetus. Of the factors examined thus far, vascular volume expansion was found to stimulate the release of atrial natriuretic factor[6, 7]; this effect was potentiated by fetal hyperosmolality.[8] In addition, hypoxia has been shown to be a potent stimulus for elevating plasma atrial natriuretic factor concentration in the ovine fetus.[9] On the other hand, conditions in which fetal plasma atrial natriuretic factor levels are suppressed have not been described. In the ovine fetus, circulating atrial natriuretic factor concentrations are significantly higher than those in adult sheep,[1, 10] and it is not known whether this high level of atrial natriuretic factor can be reduced under physiologic conditions. Expansion of vascular volume in the fetus increases plasma atrial natriuretic factor concentrations, therefore the reverse situation of blood volume reduction may decrease plasma atrial natriuretic factor levels. To test this hypothesis, we examined the effect of hemorrhage on the normally high plasma atrial natriuretic factor concentration in the ovine fetus.

Material and methods

Pregnant ewes with singleton fetuses were studied in an experimental protocol approved by the University of California, San Diego, committee on animal research. We adhered to the guidelines of the University and the National Institutes of Health for the care and use of these animals. The fetuses were implanted with chronic indwelling arterial, venous, and amniotic fluid catheters. Surgical preparation, care, and postoperative antibiotic regimen have been described in detail elsewhere.[6] The experiments began 5 or 6 days after surgery when the fetal gestational age was 109 to 138 days (term = 145 to 150 days). During the experiment fetal arterial pressure, venous pressure, heart rate, and amniotic fluid pressure were continuously recorded on an on-line computer, as described previously.[11]

To investigate the effect of blood removal because of sampling on plasma atrial natriuretic factor concentra-

tions, 104 animals were studied. Most animals were studied once, and some were studied twice on two different days, separated by a minimum of 48 hours. Under basal conditions, two consecutive blood samples of 3.5 ml each (an average of approximately 1% of the circulating fetal blood volume) were taken at 15- to 30-minute intervals for atrial natriuretic factor measurements. In one group of fetuses, the blood volume removed for the first sample was not replaced with fluid or maternal blood. In the other group, the volume removed was replaced with an equal volume of maternal blood. In most of these paired blood samples, plasma arginine vasopressin concentrations were also measured. In addition, angiotensin II concentrations were measured in some of these paired samples. Other data obtained from the animals used for the sampling study have been presented in several of our recent reports.[4, 6, 9, 12-16]

In the hemorrhage experiments, 10 fetuses were studied. The protocol consisted of a 30-minute control period, a rapid continuous hemorrhage over 10 minutes, and a 6-hour recovery period. At 24 to 25 hours after hemorrhage, all variables were monitored. During the control period and at 24 hours after hemorrhage, the volume of blood circulating in the fetus was measured with technetium 99–labeled autologous fetal red blood cells.[17] At intermediate times, blood volumes were calculated from the hematocrits after corrections for volume of red blood cells removed in sampling as previously described.[18] Fetal blood samples of 4 ml each were taken at 10 and 30 minutes during the control period, at the end of hemorrhage, and at 1.5, 3.5, 5.5, 24, and 25 hours after hemorrhage for measurements of fetal blood gases and pH (blood gas analyzer model 1302, 39.5° C, Instrumentation Laboratory, Lexington, Mass.), microhematocrit in triplicate, and plasma atrial natriuretic factor concentrations. Additional blood samples of 1 ml each were taken at 20 minutes during the control period and 2.5, 4.5, 6.5, and 24.5 hours for hematocrit determinations. Parts of the results on fetal blood volume restoration, hematocrits, and cardiovascular changes after hemorrhage have been presented in detail elsewhere.[14]

The concentration of atrial natriuretic factor in the plasma was measured by radioimmunoassay methods previously described.[6] The plasma samples were extracted with reverse phase C_{18} microcolumns (Sep-Pak, Waters Associates, Milford, Mass.). The recovery of the extraction procedure determined by the addition of 100 pg atrial natriuretic factor to fetal plasma averaged 91%. The extracted samples were reconstituted in buffer, and atrial natriuretic factor concentrations were measured with an antibody generated against human atrial natriuretic factor 1-28 (Peninsula Laboratories, Belmont, Calif.). Human atrial natriuretic factor 1-28 was used for the standard and the tracer. The interassay and intraassay coefficients of variation were 9.5% and 4.5%, respectively. Plasma arginine vasopressin and angiotensin II concentrations were measured by radioimmunoassay procedures reported previously.[6, 12]

The data are presented as mean ± SE. Each variable was analyzed for significance in changes with time by using a two-way analysis of variance for repeated measures, with time and animal as the two factors. If the changes were significant, the individual means were compared using Fisher's least significant difference test for multiple comparisons. To explore relationships between variables, standard bivariate and multivariate linear regression analyses were performed. The paired Student t test was used to analyze hormone concentrations in the two consecutive blood samples under basal conditions.

Results

Effect of blood sampling. In two groups of fetuses between the gestational ages of 109 and 138 days, two consecutive blood samples of 3.5 ml each were taken under basal conditions at 15- to 30-minute intervals. In the group in which the blood withdrawn for the first sample was not replaced with fluid or maternal blood, plasma atrial natriuretic factor concentration decreased significantly from the first to the second sample by 17 ± 7 pg/ml, a 9.6% increase ($p < 0.02$, Table I). In the group in which the blood removed during the first sample was replaced with an equal volume of maternal blood, plasma atrial natriuretic factor concentration did not differ from the first to the second sample ($p = 0.84$). In both groups of fetuses, neither plasma arginine vasopressin nor angiotensin II concentrations changed significantly from the first to the second sample (Table I). There were no significant differences in the concentration of the first sample between the two groups for each of the three hormones.

Effect of hemorrhage. In the 10 fetuses at 113 to 134 days' gestation, an average of 21.0% ± 1.7% of their initial blood volume (range 13.5% to 29.8%) was removed over a 10-minute period. Control fetal blood volume was 110.8 ± 1.8 ml/kg. At the end of hemorrhage, blood volume was reduced to 93.6 ± 2.3 ml/kg, a 15.0% decrease ($F = 18.6, p < 0.0001$, Table II). Blood volume remained significantly below control levels for 5.5 hours after hemorrhage. At 6.5 hours after hemorrhage, fetal blood volume returned to levels not significantly different from the control levels (Fig. 1).

Mean plasma atrial natriuretic factor concentration in the fetuses during the 30-minute control period before hemorrhage was 139 ± 9 pg/ml (Table II). The atrial natriuretic factor concentration in the second

Blood volume (ml/kg)	110.8 ± 1.8	93.6 ± 2.3*	95.4 ± 2.3*	105.5 ± 3.5‡
Plasma ANF (pg/ml)	139 ± 9	110 ± 9‡	97 ± 8§	119 ± 6

Values expressed as mean ± SE in 10 fetuses. *ANF,* Atrial natriuretic factor.

*$p < 0.0001$, as compared with control of same variable.

†$p < 0.01$, as compared with control of same variable.

‡$p < 0.05$, as compared with control of same variable.

§$p < 0.001$, as compared with control of same variable.

control sample was lower than that in the first control sample in each of the 10 fetuses, with the mean decrease being 12.0 ± 2.5 pg/ml ($p < 0.001$). In response to hemorrhage, plasma atrial natriuretic factor concentration decreased significantly to 110 ± 9 pg/ml at the end of hemorrhage and continued to decrease further to 97 ± 8 pg/ml at 1.5 hours after hemorrhage (F = 7.78, $p < 0.0001$). This represents a decrease of 30.2% in plasma atrial natriuretic factor concentrations. Thereafter, atrial natriuretic factor slowly returned to basal level; by 5.5 hours after hemorrhage, plasma atrial natriuretic factor concentration was not significantly different from the control levels (Table II, Fig. 2). To determine the relationship between fetal blood volume and plasma atrial natriuretic factor concentration, bivariate regression analysis was performed with data obtained at the end of hemorrhage. The analysis showed that the hemorrhage-induced decrease in plasma atrial natriuretic factor concentration was significantly correlated with the percentage of reduction in blood volume ($r = 0.665$, $p < 0.05$; Fig. 3).

Fetal cardiovascular parameters during control, hemorrhage, and recovery periods are shown in Table II. Arterial pressure fell significantly at the end of hemorrhage, returned to control levels at 1.5 hours after the hemorrhage, and decreased below control levels throughout the remaining recovery period (F = 7.00, $p < 0.0001$). Fetal venous pressure decreased during hemorrhage and decreased further by 0.7 ± 0.3 mm Hg at 30 minutes after hemorrhage (F = 2.09, $p < 0.05$). This decrease was transient; venous pressure returned to basal levels by 1.5 hours after hemorrhage. Fetal heart rate decreased significantly at the end of hemorrhage (F = 2.90, $p < 0.01$), but returned to control levels 1.5 hours after the hemorrhage. Multivariate regression analysis, showed that there was no correla-

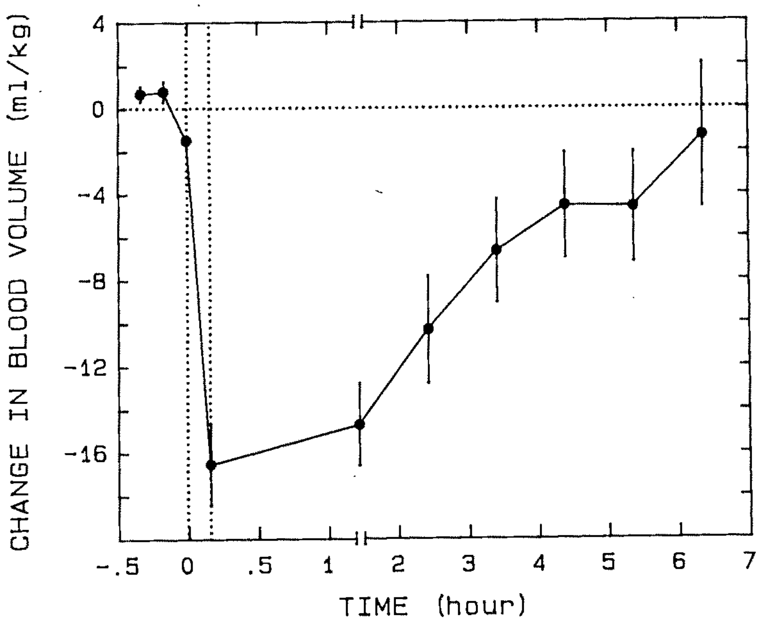

Fig. 1. Hemorrhage-induced changes (mean ± SE, $n = 10$) in blood volume in ovine fetuses at 125 ± 2 days' gestation. Fall in blood volume during and after hemorrhage, analyzed by two-way analysis of variance, was significant (F = 18.6, $p < 0.0001$). *Vertical dotted lines* mark beginning and end of hemorrhage.

tion between the change in plasma atrial natriuretic factor concentration observed at the end of hemorrhage and the change in venous pressure or heart rate.

Fetal blood gas changes during and after hemorrhage are shown in Table II. Arterial Po_2 and pH fell significantly at the end of hemorrhage and remained low throughout the 6-hour recovery period (F = 7.21, $p < 0.0001$ for Po_2; F = 7.64, $p < 0.0001$ for pH). Arterial Pco_2 increased significantly at the end of hemorrhage and was elevated during the entire recovery period (F = 7.64, $p < 0.0001$). Plasma osmolality after hemorrhage underwent a small but significant increase from control levels (F = 2.3, $p < 0.05$). No significant correlation was found between the decrease in plasma atrial natriuretic factor concentration and the change in blood gases, pH, or osmolality (bivariate and multivariate regression analyses).

All 10 fetuses survived the hemorrhage and were alive at the end of the 6-hour recovery period. Three of the fetuses died overnight; at 24 hours after hemorrhage, only seven fetuses were alive. The cardiovascular and blood gas values for these seven fetuses during the prehemorrhage control period and at 24 hours after the hemorrhage are shown in Table III. Arterial pressure, venous pressure, and heart rate at 24 hours after hemorrhage were not different from those during the control period. Plasma osmolality remained within normal range. However, fetal blood gases and pH underwent significant changes at 24 hours. Arterial Po_2 and pH were significantly reduced (F = 11.78, $p < 0.001$; and F = 3.16, $p < 0.05$, respectively) and Pco_2 was elevated (F = 8.23, $p < 0.001$). Surprisingly, fetal blood volume was significantly below control levels (F = 8.23, $p < 0.001$), while plasma atrial natriuretic factor concentration was significantly elevated (F = 5.19, $p < 0.001$) (Table III).

To explore the factors that might have contributed to the increase in plasma atrial natriuretic factor 24 hours after the hemorrhage, multivariate and bivariate regression analyses were performed. The results showed that the increase in atrial natriuretic factor concentration at 24 hours was not significantly correlated with the change in arterial Po_2, osmolality, blood volume, venous pressure, or heart rate.

Comment

The concentration of atrial natriuretic factor in ovine fetal circulation under basal conditions is four to five times higher than that in pregnant adult sheep.[1] Available evidence suggests that the regulation of atrial natriuretic factor release in the fetal animal is essentially similar to that in the adult. Blood volume expansion is a stimulus for elevating plasma atrial natriuretic factor concentrations in the fetus,[6, 7] although the fetal response was more transient than that of the adult.[19] This study demonstrated conversely that blood volume reduction can decrease plasma atrial natriuretic factor concentration, suggesting that blood volume is an important determinant of plasma atrial natriuretic factor concentrations in the fetus.

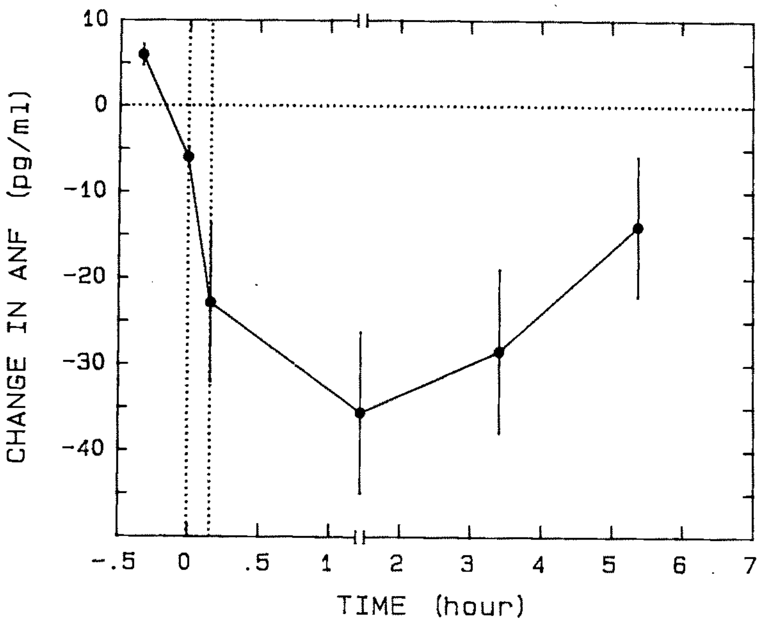

Fig. 2. Change (mean ± SE, $n = 10$) in plasma atrial natriuretic factor concentrations in ovine fetuses during and after hemorrhage. Plasma atrial natriuretic factor at end of and at 1.5 hours after hemorrhage were significantly suppressed from control levels ($F = 7.78$, $p < 0.0001$, analysis of variance). *Vertical dotted lines* mark beginning and end of hemorrhage.

Previous studies have investigated the effects of hemorrhage on plasma atrial natriuretic factor levels in adults of different species. However, the results have been inconclusive in that atrial natriuretic factor levels after hemorrhage were either elevated, suppressed, or unchanged. In a study in human beings,[20] removal of up to 1000 ml of blood over a 30-minute period had no significant effect on plasma atrial natriuretic factor levels; in the sheep, plasma atrial natriuretic factor concentrations did not change during or after a hemorrhage of 15 ml/kg over a 10-minute period.[21]

On the other hand, in pigs in which 40% of the calculated blood volume was removed over a 30-minute period, plasma atrial natriuretic factor concentrations increased significantly even though atrial pressure fell.[22, 23] In contrast, hemorrhage in dogs,[24] rats,[25] and rabbits[26] and blood donation in humans[27] resulted in falling plasma atrial natriuretic factor levels. Consistent with these latter observations, our study in the fetus demonstrated that an acute hemorrhage of 21% of initial blood volume over a 10-minute period significantly reduced plasma atrial natriuretic factor concentrations. At the end of hemorrhage, the decrease in plasma atrial natriuretic factor was significantly correlated with the decrease in fetal blood volume. Blood volume reached the lowest value of 15% of initial blood volume at the end of hemorrhage and remained low for the first 2 hours of the recovery period.

In parallel with this fall in blood volume, plasma atrial natriuretic factor concentrations were lowest during the same time period. With the restoration of fetal blood volume to normal at the end of the 6-hour recovery period, plasma atrial natriuretic factor levels gradually returned to normal. These observations strongly suggest that fetal blood loss was part of the cause for the reduction in plasma atrial natriuretic factor concentrations. However, factors in addition to blood volume appear to be important in that only 42% of the variations in plasma atrial natriuretic factor concentration can be attributed to the blood volume changes as determined by regression analysis (Fig. 3). Findings similar to ours were reported in a recent study in pigs in which a hemorrhage of 14 ml/kg over 5 minutes significantly decreased plasma atrial natriuretic factor levels in the recovery period.[28] Whether the decrease in plasma atrial natriuretic factor concentration was caused by a decrease in secretion or an increase in the clearance rate of atrial natriuretic factor or both was not known, although a reduced secretion seems most likely because of the reduction in venous pressure.

During hemorrhage, fetal arterial pressure decreased and was suppressed during the recovery period. Venous pressure and heart rate fell significantly, but transiently. These changes in vascular pressures were consistent with our earlier report in ovine fetuses subjected to acute hemorrhages of 14% of initial blood volume over a 5-minute period.[18] However blood volume restoration in our study occurred more slowly than in the previous study, possibly because the hemorrhage in our present study was more severe. In addition, blood sampling continued after the hemorrhage at reg-

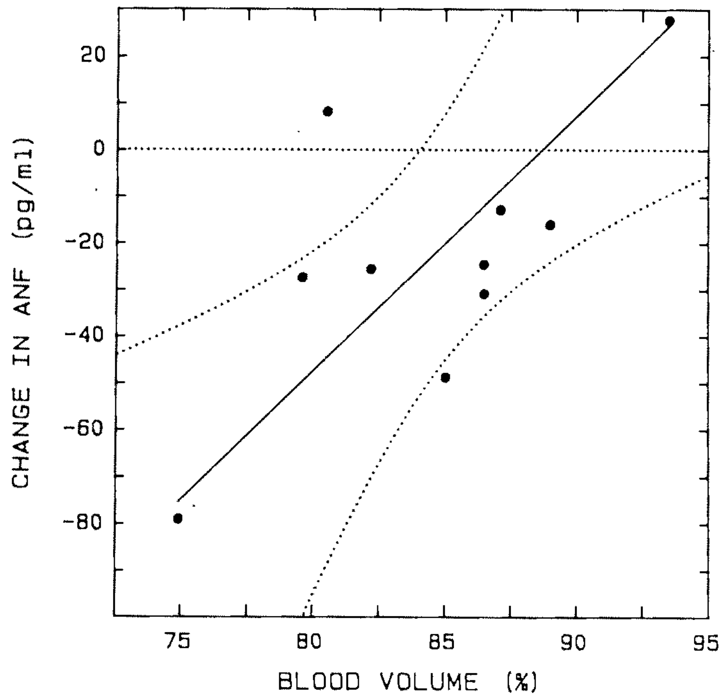

Fig. 3. Correlation between changes in plasma atrial natriuretic factor concentrations and blood volume at end of hemorrhage in ovine fetuses ($r = 0.649$, $p < 0.05$). The 95% confidence interval about the regression line is shown.

ular intervals at a volume of 4 ml per sample, which might cause partial depletion of the volume restored after the initial hemorrhage. A significant relationship between the fall in plasma atrial natriuretic factor levels and the cardiovascular or blood gas changes during hemorrhage was not observed with any of these variables. Furthermore, the gestational age of the fetus had no effect on the changes of these variables during and after hemorrhage. Thus blood volume appeared to be primarily responsible for the decrease in plasma atrial natriuretic factor concentrations during and after hemorrhage. However, the fall in venous pressure during the immediate period after hemorrhage might contribute to the fall in plasma atrial natriuretic factor levels at that time.

At 6 hours after hemorrhage, all cardiovascular variables, blood volume, and plasma atrial natriuretic factor levels had returned to normal. However, at 24 hours after hemorrhage, fetal blood volume was significantly below control volume, and plasma atrial natriuretic factor concentrations were elevated to 230% of control. Thus plasma atrial natriuretic factor increased even though it had decreased immediately after hemorrhage and even though blood volume was reduced. Under these conditions, factors other than blood volume must be responsible for the elevated atrial natriuretic factor concentrations. A possible explanation for the elevated levels of atrial natriuretic factor at 24 hours is a decrease in renal clearance of atrial natriuretic factor in these hypoxic and acidotic fetuses. Acidemia has been shown to decrease blood flow to the kidney,[29] decreasing renal clearance; however, this would only account for a small portion of the rise in plasma atrial natriuretic factor concentrations because the fetal kidneys contribute minimally to the plasma clearance of atrial natriuretic factor.[30]

In evaluating other factors which might have contributed to the increase in plasma atrial natriuretic factor levels at 24 hours, we have previously reported that hypoxia is a potent stimulus for the release of atrial natriuretic factor in the ovine fetus.[9] In addition, hyperosmolality can directly stimulate the fetal atria to release atrial natriuretic factor and potentiate the effect of vascular volume expansion on atrial natriuretic factor release.[8] However, when these possibilities were explored in the present study using regression analysis, the increase in atrial natriuretic factor at 24 hours was not significantly correlated with the decrease in arterial Po_2 or plasma osmolality. We have also observed an increase in plasma arginine vasopressin concentrations in these fetuses 24 hours after hemorrhage.[14] This rise could stimulate the release of atrial natriuretic factor; however, this possibility is unlikely because pharmacologic concentrations of arginine vasopressin are required for the release of atrial natriuretic factor[31]; the rise in arginine vasopressin observed in these studies was within the physiologic range. Furthermore, arginine vasopressin primarily releases atrial natriuretic factor through its pressor effects; in our studies the vascular pressures were not elevated at any time after hemorrhage.[14]

These findings suggest that, under the condition of blood loss and volume restoration, the regulation of atrial natriuretic factor release could be multifactorial. Whereas volume reduction and decreases in venous pressure tended to lower atrial natriuretic factor release, factors such as reduced renal clearance, hypoxia, and hyperosmolality tended to enhance atrial natriuretic factor release. The observed changes in atrial natriuretic factor levels could be the result of these interactive mechanisms.

To determine the sensitivity of the effect of blood volume on plasma atrial natriuretic factor concentrations, we examined 167 pairs of consecutive fetal blood samples for the effect of blood sampling on plasma atrial natriuretic factor levels under basal conditions. Removal of 3.5 ml of fetal blood without volume replacement (that is, removal of approximately 1% of fetal blood volume) resulted in the significantly decreased plasma atrial natriuretic factor concentrations seen when the blood was resampled 15 to 30 minutes later. However, if the blood was replaced with an equal volume of maternal blood, plasma atrial natriuretic factor concentration remained unchanged during the same time period. In contrast, plasma arginine vasopressin and angiotensin II were not affected by the two sampling procedures regardless of whether blood was replaced. In a previous study in which ovine fetuses were subjected to slow hemorrhage over 2 hours, we found that plasma renin activity, arginine vasopressin, and norepinephrine concentrations increased significantly only after removal of 5% to 10%, 10% to 15%, and 20% to 30%, respectively, of the initial fetal blood volume.[32] In the current study, plasma atrial natriuretic factor concentrations decreased significantly after removal of only 1% of fetal blood volume; this decrease suggests that fetal atrial natriuretic factor may be more sensitive to changes in blood volume than other vasoactive hormones. We are surprised by this finding and have no explanation for the observation that plasma atrial natriuretic factor, but not arginine vasopressin or angiotensin II, was responsive to such small blood volume changes.

In adults, the mechanism responsible for the release of atrial natriuretic factor during blood volume expansion appears to be atrial stretching. The increase in vascular volume elevates venous return, resulting in a rise in right atrial pressure and an increase in atrial stretch, which in turn initiates the release of atrial natriuretic factor from atrial myocytes.[33] Presumably, the same mechanism would operate in the fetus. The finding that a decrease in fetal blood volume lowers plasma atrial natriuretic factor concentrations suggests that atrial natriuretic factor is normally released in the fetus as a result of a stimulated state, which is consistent with the observation that basal plasma atrial natriuretic factor levels in rat,[3] sheep,[1] and human[34] fetuses are significantly higher than such levels in adults of the same species.

Our study suggests that the basal level of atrial natriuretic factor in fetal circulation is normally released as a result of a stimulated state and that fetal plasma atrial natriuretic factor can be reduced by blood volume removal.

LETTERS TO THE EDITORS

Prediction of survival of infants weighing <800 grams at birth: Errors in the application of multivariate statistical techniques

To the Editors: The development and validation of a practical and accurate prognostic model in extremely low birth weight infants represents an important challenge for modern medicine. In the article by Lipper et al. (Lipper EG, Ross GS, Auld PAM, Glassman MB. Survival and outcome of infants weighing <800 grams at birth. AM J OBSTET GYNECOL 1990;163:146-50) the authors have presented a multivariate predictor of mortality in extremely low birth weight infants. Unfortunately, there are several important methodologic flaws in their model. Fully 21 "independent" variables were entered into the multiple logistic regression equation examining 80 inborn extremely low birth weight infants, with an unspecified number of outcome events (i.e., deaths). No univariate analysis comparing differences in these 21 variables between survivors and nonsurvivors was presented. To support a multivariate examination of 21 variables, between 105[1,2] and 210[3] outcome events (deaths) would have been required. We are told that 41 of all 184 extremely low birth weight infants admitted to the Neonatal Intensive Care Unit were discharged home, so we know that 77.7% died. Therefore we can estimate that approximately 62 of the 80 inborn infants died (i.e., there were approximately 62 outcome events).

Clearly, the sample size is too small to support the type of analysis reported. Furthermore, the authors state that the "independent variables were examined for multicollinearity and no serious collinearity problems were found." It is difficult to accept this statement at face value because there is a high degree of correlation between many of the infant variables included (e.g., length of gestation, birth weight, crown-heel length, and head circumference). For example, we have previously reported a correlation as high as 0.87 (Pearson correlation coefficient) between birth weight and crown-heel length in infants who weigh <1500 gm at birth[4] and we would not be surprised if there were a similar high correlation between 5-minute Apgar score and initial pH value.

In their discussion of other prognostic models, the authors erroneously comment that "the definition of viability was not specified" in the article by Ales et al.[4] The methods section of that article[4] plainly states that all live-born singleton infants who weighed ≤1500 gm at birth were included with the exception of six infants "with abnormalities incompatible with life (i.e., Potter's syndrome, anencephaly, encephalomyelomeningocoele, thanatophoric dysplasia syndrome, huge pelvic and sacrococcygeal teratomas)."[4] Table II in that article[4] documents that 22% (36/158) of the infants in the derivation data set weighed ≤800 gm at birth. Infants who died soon after delivery were not excluded. Because this was not a prospective study and uniformity of timing or circumstances for obtaining initial pH value could not be assured, initial pH value was not considered in the multivariate model. However, the model, based on birth weight and 5-minute Apgar score, had a predictive accuracy of 84.5% and was validated in a separate cohort of very low birth weight infants.

Although initial pH value and 5-minute Apgar score intuitively sound like reasonable candidates for significant predictors, the stability of the multivariate model reported in Lipper's article is of enormous concern, given the number of variables considered and the high correlations between many of the infant variables. We suggest that the authors reexamine their data after studying the univariate differences between survivors and nonsurvivors and clarifying correlations among all variables being considered for the multivariate model. Only then should they select at most six to 12 truly independent variables for inclusion in their multivariate model. Finally, it is of the utmost importance to validate prognostic models in separate data sets.

Reply

To the Editors: Our study represented the cumulation of 5 years of data (1980 to 1985) in which we were able to examine the effect of maternal and perinatal variables on mortality in 80 inborn extremely low birth weight infants. Ideally, we would have preferred a larger sample for what we intended to be the exploratory phase of our study. We are currently compiling data for the second half of the 1980s, which should enable us to validate the predictor model in a second, confirmatory (i.e., independent) data set.

In terms of the examination of our variables for multicollinearity, we stand true to our statement that no serious collinearity problems were found. The restriction of the population under investigation to a birth weight of 500 to 799 gm results in a reduction in the variance of other independent variables. Therefore the correlations among these variables were not suggestive of collinearity, with the exception of the Apgar score at 1 and 5 minutes in which the correlation was 0.78, which would of course be expected. The next largest correlation was between head circumference and gestational age (0.65); no other correlation was higher than 0.56.

Finally, we did not intend to misquote the article by Ales et al. It was not clear from the manuscript whether infants <800 gm who died shortly after birth were excluded. Now this point has certainly been clarified by the authors.

A plea for early diagnosis of fallopian tube carcinoma: Can hysteroscopy be of use?

To the Editors: Primary carcinoma of the fallopian tube is the rarest genital malignancy, constituting 0.2% to 1% of all gynecologic cancers.[1] Hence, definitive preoperative diagnosis is rarely made and is often confused with ovarian cancer. More importantly, the diagnosis is delayed until the disease is advanced. Prognosis depends on the stage of disease.[1, 2] Early definitive diagnosis of fallopian tube carcinoma has received relatively scant attention. Tubal carcinoma, unlike ovarian, arises in a hollow viscus with muscular walls and becomes symptomatic earlier, with vaginal bleeding or discharge in 50% and pain in 30%.[1] Only 14% of patients did not have symptoms in a recent series.[2]

For early diagnosis, vaginal pool cytology is of limited value.[1] Hirai et al.[3] reported positive endometrial aspiration cytology in 60% of patients and have made a plea for repeated sampling. Also, laparoscopy has been suggested in women with postmenopausal bleeding and negative diagnostic curettage.[1] Vaginal ultrasonography with its improved resolution can be expected to detect many more tubal lesions, which should be investigated by laparoscopy.

Another commonly performed investigation in postjenopausal and dysfunctional bleeding is hysteroscopy. With the disease being extremely rare, no individual gynecologist can be expected to collect sufficient information in this regard, hence there is need for a uniform protocol. Will it be possible to suspect or diagnose tubal carcinoma on hysteroscopy? It may identify the source of abnormal discharge from the tubal openings. Salpingoscopy is limited to the exploration of the initial 5 mm of the tube (tubaloscopy) but it should certainly be possible to take aspiration from the intramural portion of tubes or tubal openings for cytology. This, in addition to endometrial aspiration and posterior vaginal pool samples, would increase the detection rate of malignant cells from tubal carcinoma. Therefore, it is suggested that particular attention be paid to tubal openings and aspiration samples be taken from these openings during hysteroscopic evaluation of abnormal bleeding when uterine cavity shows no lesion. Can we expect early definitive diagnosis of fallopian tube carcinoma in this era of endoscopy?

Egg transport through the oviduct

To the Editors: In his letter on the nature of egg transport through the oviduct Dr. Ch. Egarter (Egarter C. The complex nature of egg transport through the oviduct. AM J OBSTET GYNECOL 1990;163:687), referring to an article in the JOURNAL (Pulkkinen MO, Jaakkola U-M. Low serum progesterone levels and tubal dysfunction—A possible cause of ectopic pregnancy. AM J OBSTET GYNECOL 1989;161:934), hypothesizes that an egg can enter the contralateral fallopian tube via the uterus. In their reply, Drs. Pulkkinen and Jaakkola assert that this mechanism seems unlikely and is not supported by experimental findings.

This may be true; however, the possibility of this uncommon mechanism is supported by clinical observations. According to Marchesi[1] the ovum may sometimes pass through the fundal region of the uterus and enter the contralateral oviduct (the author calls this phenomenon "internal migration"). That is the only possibility to explain the observed cases of ectopic pregnancies implanted in an oviduct whose distal extremity was certainly occluded or even had been resected during a previous surgery. Although this is an uncommon event, it cannot be excluded.

This confirms that the nature of the transport of the egg through the oviduct is very complex and many factors that are not well known today are involved.

Relaxation of the human uterine artery by atrial natriuretic peptide is independent of the endothelium

To the Editors: Atrial natriuretic peptide is a 28 amino acid peptide produced in the right atrium and known to induce diuresis, vasorelaxation, and hypotension.[1] An intact vascular endothelium is necessary for the vasodilation induced by acetylcholine, and this relaxation of vascular smooth muscle is mediated by the release

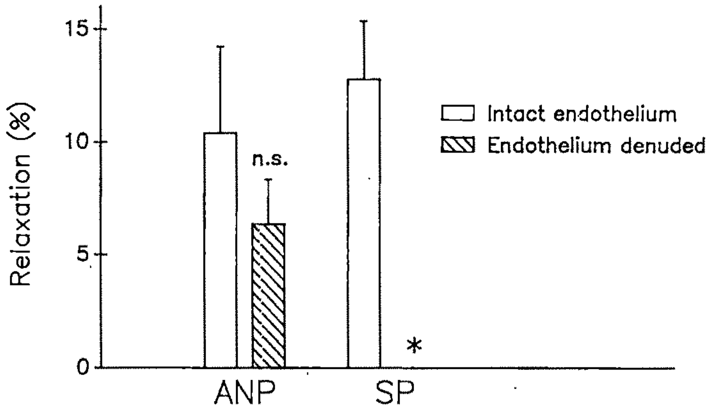

Fig. 1. Induction of relaxation by atrial natriuretic peptide and substance P in vessels with endothelium intact and denuded.

of the so-called endothelium-derived relaxing factor,[2] now identified as nitric oxide. Other signal substances that act by means of endothelium-derived relaxing factor to induce vasodilation are adenosine triphosphate, substance P, bradykinin, and histamine. On the other hand, calcitonin gene-related peptide and vasoactive intestinal polypeptide have been shown to relax vascular smooth muscle independently of an intact endothelium. This investigation was undertaken to elucidate whether atrial natriuretic peptide–induced relaxation of the human uterine artery is related to the vascular endothelium.

Preparations were obtained from eight women (mean age 47 years, range 34 to 64 years) undergoing abdominal hysterectomy for benign gynecologic diseases. The patients were informed of the investigation and had given their consent to excision of the preparations. The uterine arteries were cut into circular preparations that were mounted in organ chambers, containing Krebs-Ringer solution. The mechanical activity was recorded by means of a Grass FT03C force-displacement transducer on a Grass model 7D polygraph (Grass Instruments Co., Quincy, Mass.). The preparations were contracted by exchanging the sodium chloride in the bathing fluid with potassium chloride, and when a stable contraction was established atrial natriuretic peptide (10^{-7} mol/L) was added to the organ chamber. After registration of possible effects the preparations were washed. Then the endothelium was removed from some of the vascular preparations by twice gently injecting the oxygen-carbon dioxide gas mixture through the vessel lumen with a 0.3 mm cannula during 5 to 10 minutes at an interval of 10 minutes. The correlation between the removal of endothelium and the failure of the artery, precontracted by potassium, to relax when exposed to substance P (10^{-7} mol/L) was very strong. Hence absence of the relaxatory effect of substance P was taken as proof of successful removal of the endothelium. After the vessels had been denuded of their endothelium the effect of atrial natriuretic peptide (10^{-7} mol/L) was tested again. The Wilcoxon signed rank test was used to evaluate possible significant differences.

Atrial natriuretic peptide reduced smooth muscular tone in vessels precontracted by potassium chloride ($p < 0.05$). The relaxation was 10.4 ± 3.85% of the potassium-induced contraction ($n = 8$). After removal of the endothelium the isolated vessels still responded with a contraction to potassium chloride depolarization, indicating no damage to the smooth musculature. Both preparations with an intact endothelium and those denuded of it responded with relaxation when exposed to atrial natriuretic peptide. There was no significant difference between the effect of atrial natriuretic peptide in those two types of isolated uterine arteries. In contrast, substance P failed to induce relaxation in vessels from which the endothelium had been removed. The results are illustrated in Fig. 1.

In conclusion, atrial natriuretic peptide relaxes the vascular smooth musculature of the isolated human uterine artery by an endothelium-independent mechanism, which does not involve endothelium-derived relaxing factor, recently characterized as nitric oxide.

Breast disease management in an obstetrics and gynecology department

To the Editors: We read with great interest the article by Hall et al. (Hall JA, Hall BR, Murphy DC, Hall KA.

Surgical management of breast disease in an obstetrics and gynecology group. AM J OBSTET GYNECOL 1990;162:1526-30), and we would like to express our opinion on this subject and to describe our Breast Unit, which is part of the 1st Obstetrics and Gynecological Department, University of Athens, and is staffed by gynecologists.

We agree that breast diseases can be diagnosed by each doctor who first examines a woman. Breast examination is routine for gynecologists, who are more familiar than other doctors with the philosophy of screening tests, such as Papanicolaou tests. They also have adequate surgical skills. Therefore in our opinion gynecologists are able to offer both diagnostic and surgical treatment of breast diseases. However, we think that breast cancer treatment must be done by a cancer specialist, who deals exclusively with oncology and can be gynecologist-oncologist or surgical oncologist. This person is responsible for the patient's follow-up and for collaborating with the radiotherapist or chemotherapist as a team. Regarding the type of primary operation, breast conservation procedures can be effectively accomplished only in specialized units, because they involve accurate evaluation of a variety of clinical and biologic factors affecting the mode of cancer treatment.

Our unit was founded in 1979. There is an outpatient department for routine breast examination and follow-up of patients. Mammography is provided by the hospital's radiology group and mammograms are reviewed by our group.[1] Radiotherapy is performed by the hospital radiotherapists, but chemotherapy, when required, is performed by us. During these years 2490 breast biopsies were done and 830 cases of breast cancer were identified and operations were performed. Our treatment of choice for breast cancer is a conservation procedure, when appropriate, for better cosmetic results. Of course, we perform modified radical or radical mastectomy in other cases. In all cases a complete axillary node dissection is performed at three levels. The total number of dissected nodes is 32.59 ± 9.43 (mean ± SD) and their distribution is 22.86 ± 7.09 at low level, 3.28 ± 3.51 at mid level, and 6.25 ± 4.26 at apical level.

In conclusion, a gynecologist, when appropriately trained, can offer primary care for the breast, as well as surgical treatment and follow-up of breast cancer.

Antony Keramopoulos, MD, Christina Tsionou, MD, Demetrios Minaretzis, MD, and Dionysios Aravantinos, MD
1st Obstetrics and Gynecological Department, University of Athens, "Alexandra" Maternity Hospital, 80 Vas. Sophias Ave., 115 28 Athens, Greece

REFERENCE

Reply

To the Editors: I would agree with Keramopoulos et al. that the gynecologist can offer primary care and surgical treatment for breast disease. With the new American Cancer Society data stating that as many as 1 in 9 American women may have breast cancer in their lifetime, it is obvious that the gynecologist needs to become involved.

I would disagree that the surgeon performing breast cancer treatment needs to limit his practice to this field. I believe that the surgery should be performed by an adequately trained surgeon, and I feel that is within the expertise of the gynecologic surgeon. Obviously training programs need to be established to accomplish this goal.

Axillary lymph node dissection is performed for staging purposes only. The identification of malignant lymph nodes in the axilla indicates systemic disease, and removal of those lymph nodes is not necessarily a curative operation. Therefore the number of lymph nodes removed in an adequate sample needs to be only enough to provide information on staging. Five to 10 axillary nodes carefully examined by the pathologist will provide as much information as removal of 25 to 30 lymph nodes. The patient with malignant axillary nodes has no better chance of survival if she has a large number of lymph nodes removed than if she has only a few lymph nodes removed. The importance of the axillary node dissection is only to identify the existence of spread of the cancer into the lymphatics. An axillary node dissection that does not yield malignant nodes fails to guarantee the absence of metastatic disease. Axillary node dissection with large numbers of lymph nodes removed, as mentioned by Keramopoulos et al. (approximately 32), indicates thoroughness but removes more axillary tissue than is necessary for staging and greatly increases the complexity of the operation. Removal of a large number of lymph nodes also may increase complications from arm edema and may restrict the radiotherapist from treating the axilla. A dissection of level I nodes can be performed readily and yields an adequate staging sample of approximately 10 nodes without a great risk of long-term adverse sequelae to the patient.

It is time for the gynecologist to become more involved in breast disease. It is also time to recognize that early diagnosis is necessary for survival because of the systemic nature of breast cancer very early in its development.

Untreated luteal phase deficiency as another possible risk factor for preterm delivery

To the Editors: We read with interest the article by McGregor et al. (McGregor JA, French JI, Richter R, et al. Antenatal microbiologic and maternal risk factors associated with prematurity. AM J OBSTET GYNECOL 1990;163:1465-73). Risk factors for prematurity included infectious causes, maternal medical problems, antepartum treatment for urinary tract infection, prior preterm delivery, bacterial vaginosis (all of which were positively associated with preterm delivery), and factors of maternal age, prior abortion (therapeutic or spontaneous), and fetal sex. Although only 9 (4.5%) of 202 women were delivered at <37 weeks, certain small groups seemed to be associated with higher risks: women aged 30 to 38 years (2/20, 10%), prior preterm birth (4/21, 19%), and *Mycoplasma hominis* infection (3/18, 17%).

We evaluated 540 women who had preterm histories of luteal phase defects but who were eventually able to conceive; 82 (15%) of 540 were delivered at <37 weeks' gestation. This relatively high rate (compared with 4.5% in the study of McGregor et al.) might be attributed to a relatively older group of women (mean age 32 years). We divided the 540 patients into three groups: 32 patients who refused the suggested progesterone therapy (group 1), 469 women who had progesterone therapy for ≥12 weeks (group 2), and 39 patients who took progesterone for ≥6 but <10 weeks (group 3). The rates of prematurity (<37 weeks) were 31.2% for group 1, 13.7% for group 2 ($p < 0.05$ comparing groups 1 and 2), and 10.3% for group 3. The rates of severe prematurity (<32 weeks) were 12.5% for group 1, 1.3% for group 2 ($p < 0.01$ comparing groups 1 and 2), and 2.6% for group 3. The number (mean ± SE) of days delivered early was −16.0 ± 26.8 for group 1, compared with −7.3 ± 13.0 in group 2 and −5.5 ± 16.1 in group 3 ($p < 0.01$ comparing group 1 with either group 2 or group 3). No significant differences (mean ± SE) were found in birth weights (3113 ± 874 gm for group 1, compared with 3240 ± 679 gm for group 2 and 3440 ± 646 gm for group 3).

These data, we believe, support the addition of luteal phase defects to the list of risk factors for preterm delivery. Depending on the population studied, progesterone therapy during the first trimester could prove to be one method of preventing preterm delivery.

Jerome H. Check, MD, and Grace Lee, MD

Reply

To the Editors: We appreciate the interest of Check and Lee in our prospective study of microbial factors associated with preterm (<37 weeks' gestation) birth. As noted in the article, the low rate of preterm birth (4.5%) is likely explained by our exclusion criteria: patients with recognized risks of preterm birth were excluded in this prospective cohort study of young, otherwise healthy women. Our results confirm the hypothesis that reproductive tract infection and subsequent inflammation are associated with preterm labor and rupture of membranes in some women. The results of a series of controlled trials have recently been presented.[1, 2] We calculate an overall population-attributable risk of approximately one third for preterm birth caused by infection among our patients. Further studies are required to determine which women at risk for preterm birth can benefit from indicated antimicrobial treatment or prophylaxis.

We assume that there are many other causes of preterm birth and that these should be appropriately investigated. Because of progesterone's primary endocrine role in pregnancy, interest in progesterone or progestin treatment during pregnancy is long-standing. Nevertheless, a recent metaanalysis of 20 controlled trials failed to demonstrate benefits.[3] These authors recommended that further controlled trials be limited to pregnant women with demonstrable endocrinologic abnormalities. The study of selected women (those with prior putative luteal phase defects) reported by Check and Lee demonstrated a 15% preterm birth rate, which is similar to that in unselected women at many of the publicly supported clinics we serve. We hope Check and Lee present their complete results soon.

Rapid enzyme-linked immunoassay tests for group B streptococcus infection

To the Editors: The article by Towers et al. (Towers CV, Garite TJ, Friedman WW, Pircon RA, Nageotte MP. Comparison of a rapid enzyme-linked immunosorbent assay test and the Gram stain for detection of group B streptococcus in high-risk antepartum patients. AM J OBSTET GYNECOL 1990;163:965-7) again illustrates that we have no adequate means of routine, meaningful antepartum surveillance for group B streptococcus. The shortcomings of the rapid enzyme immunoassay test are substantiated by work done at this university. In a group of approximately 100 patients, the rapid enzyme immunoassay test was used in a double-blind manner very similar to that of Towers et al. Our results were even less optimistic than theirs: When compared with the standard culture for group B streptococcus, the test was only 21% sensitive and showed a 66% specificity, with a positive predictive value of 60%. In our opinion this test has little value in identifying antepartum patients who carry the group B streptococcus bacteria.

Relationship between central venous pressure and pulmonary capillary wedge pressure in severely toxemic patients

To the Editors: In treating patients with severe toxemia Fliegner[1] emphasized fluid volume expansion to raise central venous pressure to a range between 5 and 10 cm H_2O. However, Clark[2] has observed an inconsistent relationship between central venous pressure and left-side heart pressures as estimated by pulmonary capillary wedge pressure, suggesting that it is dangerous and simplistic to rely on central venous pressure alone for fluid management in patients with severe preeclampsia.

In our intensive care unit we took 623 central venous pressure and pulmonary capillary wedge pressure measurements with a pulmonary artery catheter in 60 patients with severe preeclampsia. Of these measurements 123 were taken without treatment or fluid management (basal), and 500 were taken after hypotensor treatment (clonidine hydrochloride or diazoxide). The correlation values are shown in Table I.

Our data show acceptable values for both correlation and linear regression between central venous pressure and pulmonary capillary wedge pressure under both conditions. However, the variability of correlation values within a single patient is enormous: for a central venous pressure of 4 mm Hg, the corresponding pulmonary capillary wedge pressure values were between − 1.7 and 17.5 mm Hg. This tends to support Clark's assessment that the exclusive use of central venous pressure for fluid management in these patients is inadequate and potentially dangerous, especially if there appear to be oncotic pressure alterations with resulting pulmonary edema.[3] Our results suggest that the correlation between central venous pressure and pulmonary capillary wedge pressure is valid only when considered in a group of patients because of the variability of individual values.

Prolonged exposure to wood preservatives induces endocrine and immunologic disorders in women

To the Editors: The toxic effects of polychlorinated organic compounds are associated with spontaneous abortions, fetal malformations, growth retardation, stillbirths, thymic degeneration, reduced fertility, and changes in the menstrual cycle.[1-9]

During the postwar economic boom, wood coated with polychlorinated organic compounds containing preservatives was used for ceilings and wall panels of homes. Carpets and leather upholstery impregnated with moth repellants contained the same organic compounds. Pentachlorophenol and the γ-isomer of hexachlorocyclohexane (lindane) were thus brought into homes during modernization. The steady emission of these vapors into today's highly insulated, draft-proofed homes raises the specter of prolonged exposure because these toxins can be incorporated by inhalation, oral uptake, and skin contact. Pentachlorophenol and lindane are easily measured by capillary chromatography and mass spectroscopy. We determined whether these toxins are present in the blood of women referred for endocrinologic evaluation.

We examined 90 women with histories of habitual abortion ($n = 30$), unexplained infertility ($n = 20$), menstrual disorders ($n = 20$), or climacteric symptoms ($n = 20$). In 22 women elevated pentachlorophenol (>25 μg/L) or lindane (>100 ng/L) levels, or both, were found. This group included 8 infertile women, 6 with histories of repeated abortions; 8 women with menstrual disorders; and 6 women with climacteric symptoms and menstrual irregularities complicated by depression. The duration of exposure was shortest in infertility (mean = 4.6 years), followed by menstrual disorders (mean = 6 years) and climacteric symptoms (mean = 10 years). Pentachlorophenol and lindane were highest in women with infertility (pentachlorophenol mean = 73 μg/L, lindane mean = 250 ng/L), lower in those with menstrual dysfunction (pentachlorophenol mean = 42 μg/L, lindane mean = 210 ng/L), and lowest in patients with climacteric symptoms (pentachlorophenol mean = 48 µg/L, lindane mean = 120 ng/L). The source of the toxic vapors was identified in the residence of each patient. The pentachlorophenol concentrations in wood varied from 50 to 4000 mg/kg, and lindane concentrations were between 10 and 600 mg/kg.

Four days after the patients' spontaneous or induced menstruation we determined the concentration of follicle-stimulating hormone, luteinizing hormone, estradiol-17β, and prolactin. Thyroid (protirelin), adrenocortical (corticotropin, purified), and lymphocyte function were evaluated.

Seventeen (77%) of the 22 women were initially seen with adrenocortical malfunction: insufficiency was associated with subnormal dehydroepiandrosterone sulfate (<800 ng/ml) levels in all patients. Six (27%) women were initially seen with thyroid gland dysfunction. Immunologic disorders were observed in 15 (71%) of 21 women. In the 68 women with normal pentachlorophenol and lindane concentrations 35% (32%) were initially seen with adrenocortical malfunction (reduced lymphocyte function).

The source of intoxication was eliminated from the environments of 12 women; the exposure persisted for the remaining 10. All women received hormonal treatment and immunologic stimulation. Symptoms subsided in the 12 women with reduced polychlorinated organic compounds exposure. Menstruation normalized in all 12 patients, three of whom gave birth to healthy babies. In the 10 patients with continued exposure, blood polychlorinated organic compounds concentrations were unchanged during 2 years of observation, and treatment improved symptoms in only two. One patient conceived and had her fifth missed abortion.

We suggest that endocrine and immunologic disorders in women should alert physicians to possible exposure to pentachlorophenol and lindane. The accuracy of this diagnosis should become apparent when the familial and occupational history is reviewed. Prolonged exposure to these environmental toxins may be a factor in hirsutism, alopecia, unexplained infertility, and repeated abortions.

Pregnancy and Wilson's disease

To the Editors: The report by Dupont et al. of their case of Wilson's disease complicating pregnancy (Dupont P, Irion O, Beguin F. Pregnancy in a patient with treated Wilson's disease: A case report. AM J OBSTET GYNECOL 1990;163:1527-8) was most interesting. I recently managed two similar cases. One of the patients received treatment with zinc sulfate. This case has been reported previously.[1] The baby was delivered at 37 weeks and weighed 2700 gm at birth (25th percentile). The other was a 24-year-old primiparous patient who was known to have Wilson's disease; she was maintained on a regimen of 250 mg penicillamine four times daily. She was without symptoms at the time of conception and remained so throughout the course of pregnancy, labor, and puerperium. However, the fetus was noticed to be small and required close antenatal monitoring by nonstress tests and ultrasonographic examinations. She underwent an emergency cesarean section at 37 weeks' gestation because of fetal distress and a male baby weighing 1560 gm was delivered.

There are few reports of successful pregnancies in women with untreated, symptomatic Wilson's disease. However, from these case reports, we may conclude that those patients who received treatment and are without symptoms may be able to conceive, and a successful outcome of pregnancy is possible. In contrast to the patient described by Dupont et al., both of my patients had small babies. The fetuses of mothers with Wilson's disease should be regarded as high risk and should be closely monitored.

R.K.H. Chin, MB, BS
Department of Obstetrics and Gynaecology, Caritas Medical Centre, 111 Wing Hong St., Shamshuipo, Kowloon, Hong Kong

Reply

To the Editors: We thank Dr. Chin for his interest in our case report and we wish to comment on his remark about small babies of mothers with Wilson's disease.

We think that an expression such as "small baby" used to qualify an infant born at 37 weeks' gestation with a birth weight of 2700 gm (25th percentile) is misleading. Terms such as low-birth-weight infant or small-for-gestational-age infant should be reserved for infants born with a birth weight below 2500 gm or below the 10th percentile according to the sex, thus permitting identification of newborns at risk for neonatal complications.

Dr. Chin's second case (a male newborn weighing 1560 gm at 37 weeks' gestation) could be the first report of intrauterine growth retardation (IUGR) in a pregnancy of a patient with penicillamine-treated Wilson's disease. To date >120 pregnancies in mothers with Wilson's disease have been related. Thirty-one of these pregnancies were in untreated patients[1-4] and the remaining pregnancies were in patients treated with various chelating agents: BAL, zinc sulfate, triethylenetetramine, and especially penicillamine. No mention of IUGR is made in these reports, and all birth weights published are ≥2500 gm, except in one patient (case K.K., a normal infant weighing 2140 gm at term) reported in Walshe's series[5] of patients with triethylenetetramine-treated Wilson's disease. There is one report[6] of IUGR in a patient receiving penicillamine. She had rheumatoid arthritis and was on a regimen of 900 mg penicillamine per day. She was delivered of an abnormal male infant (lax skin, flat face, low ears, flexion contracture, inguinal hernia) weighing 2000 gm at 37 weeks' gestation; he eventually died of septicemia after abdominal surgery. In his series Walshe[5] compares the birth weights of infants of "wilsonian" mothers treated with triethylenetetramine or penicillamine. The results show a marginally higher birth weight in the triethylenetetramine group (9 patients) than in the penicillamine group (35 patients) (2900 vs 2800 gm).

Even though data in the literature are incomplete, it seems that the risk of IUGR in pregnancies of patients with treated or untreated Wilson's disease (two cases known in 120 pregnancies) is below the 3.0% to 10% risk of IUGR generally expected in the normal obstetric population. Nevertheless, in the absence of clinical studies proving the harmlessness of chelating agents in fetal development, we agree with Dr. Chin's final statement, that pregnancies in women with Wilson's disease and their fetuses should be considered as high risk and thus both should be very closely monitored.

Bound volumes available to subscribers

Bound volumes of the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY are available to subscribers (only) for the 1991 issues from the Publisher, at a cost of $61.00 for domestic, $88.27 for Canada, and $84.00 for international for Vol. 164 (January-June) and Vol. 165 (July-December). Shipping charges are included. Each bound volume contains a subject and author index and all advertising is removed. Copies are shipped within 60 days after publication of the last issue in the volume. The binding is durable buckram with the JOURNAL name, volume number, and year stamped in gold on the spine. *Payment must accompany all orders.* Contact Mosby–Year Book, Inc., Subscription Services, 11830 Westline Industrial Drive, St. Louis, MO 63146-3318, USA; phone (800) 325-4177, ext. 4351.

Subscriptions must be in force to qualify. Bound volumes are not available in place of a regular JOURNAL subscription.

GYNECOLOGIC ONCOLOGIST

Albert Einstein Medical Center (AEMC), a 600+ bed tertiary care teaching hospital, is seeking a gynecologic oncologist to establish a service in the Division of Gynecologic Oncology. AEMC is a major referral center in north Philadelphia supporting numerous post-graduate medical education programs, including a fully accredited residency program in obstetrics and gynecology. The Department of Obstetrics and Gynecology has a longstanding tradition of excellence in healthcare delivery and supports a variety of clinical research and educational activities. The Division of Gynecologic Oncology serves as a tertiary referral center within the metropolitan Philadelphia area. This service is supported by a strong Department of Radiation Oncology and a newly established Cancer Center with a state of the art facility for outpatient chemotherapy. There is also major institutional support and emphasis in research with funds and laboratory space available for basic research. The responsibilities include education, patient care and research.

AEMC is a major affiliate of Temple University. Academic appointment is available for all full-time AEMC faculty. Highly competitive salary and very attractive fringe benefits are included. Candidates must be board certified or an active candidate for board certification in the Division of Gynecologic Oncology. If you are interested in this position or would like additional information about this unique opportunity, please write to *Sze-ya Yeh, M.D., Chairman, Department of Obstetrics and Gynecology, Albert Einstein Medical Center, 5401 Old York Road, Klein #410, Philadelphia, PA 19141.* Telephone **(215) 456-6993,** FAX **(215) 456-6271.**

OBSTETRICIAN/ GYNECOLOGIST
METROPOLITAN KANSAS CITY AREA

Exceptional opportunities exist for BC/BE Obstetrician/Gynecologists in a large, expanding, independent multispecialty group. The practice is conveniently located close to hospitals, affordable luxury housing, and nationally recognized school systems. There is a strong, diversified mix of patients with an excellent referral base. A very attractive incentive package is available including a guaranteed income. Malpractice, marketing, and relocation assistance is also available. Please send curriculum vitae to:

AN INVITATION to Singapore...

for you to participate in the

XIIIth World Congress of Gynaecology and Obstetrics (FIGO) 1991

organised by the Obstetrical & Gynaecological Society of Singapore under the auspices of FIGO

This is an exclusive opportunity to attend an International Congress cum scientific exhibition which will feature 5 New Frontier Lectures, 27 Plenary sessions, 34 Symposia, 12 Debates, 21 Meet the Expert sessions, 20 Sponsored symposia, 7 Audio-visual sessions and 20 Parallel Free Communication sessions.

Prominent speakers will expound on various topics including AIDS, Genetics and Advances in Reproductive Technology and Maternity Care for the 21st Century.

The warmth and hospitality you will receive in Singapore will leave you with lasting memories of new friendships and experiences in a diverse and multi-racial culture.

Plan now to participate in an international Congress covering all aspects of obstetrics and Gynaecology.

Venue: Raffles City, Singapore
Date: 15-20 September 1991

Registration Fee:	
FIGO member	US$500
Non FIGO member	US$600
Accompanying Person	US$300

ASPEN
Medical Group

OBSTETRICIAN/GYNECOLOGIST

Aspen Medical Group is seeking additional BC/BE obstetrician/gynecologists to join staff of five. We are an independent, multispecialty group practice with 10 clinics in the Minneapolis/St. Paul metropolitan area.

- Established, challenging practice spanning the full range of obstetrics and gynecology
- Reasonable call and clinic responsibilities
- Competitive earnings
- Wide range of benefits
- No practice buy-in

For further information, please call or send your curriculum vitae to:

Nancy Borgstrom
Aspen Medical Group
Administration
1020 Bandana Boulevard West
St. Paul, MN 55108
(612) 641-7185

Equal Opportunity Employer.

Excellent opportunity to live and work in beautiful mountainous recreation area with easy access to Pittsburgh and Washington, DC areas. Davis Memorial Hospital, a modern JCAHO facility located seventy (70) miles from tertiary (WVU Hospitals), is actively recruiting a BC/BE OB-GYN wishing to establish a solo practice with coverage by two (2) well trained Board Certified OB-GYNs. Excellent potential for partnership. The practice will serve a population of 90,000. Davis Memorial Hospital is a sole community provider embarking on a major building project to include a new LDRP unit. Lucrative first year guarantee plus new office space beside hospital, staff, malpractice, etc. Elkins offers an excellent quality of life with excellent schools. It is within a one hour drive four major ski resorts. Outstanding outdoor recreational activities such as trout fishing, golf, backpacking, etc., abound. A private four (4) year liberal arts college provides many cultural amenities.

CVs and inquiries to:

James C. Stemple
Assistant CEO
Davis Memorial Hospital
P.O. Box 1484
Elkins, WV 26241
Please call collect 304-637-3151

OBSTETRICIAN/ GYNECOLOGISTS

Group Health Association, one of Washington, D.C.'s most respected names in the health maintenance field, has immediate and future openings for board certified or eligible Obstetrician/ Gynecologists.

Consisting of nine multi-specialty medical centers and 200 physicians, Group Health's highly skilled support staff serves over 150,000 members. This staff attends to the details of clinical administration, allowing you the freedom to devote your energy to practicing medicine. Further, GHA's challenging work environment offers a diverse patient population and affiliation with the area's finest hospitals.

A generous benefits package including vacation, sick leave and insurance coverage (malpractice, life, retirement, disability and dental) awaits you in return for your expertise. In addition, you can look forward to company-paid hospital and licensing fees, professional society dues, continuing education as well as predictable office hours.

If you would like more information, please send your C.V. to the address below or call Mary Hines, Physician Recruiter, on 1-800-336-1442 or in DC Metro area, (202) 364-7442.

CHAIR, DEPARTMENT OF OB-GYN

An 830-bed regional tertiary care teaching hospital is seeking a Chair for its Department of OB-GYN. The Allentown Hospital–Lehigh Valley Hospital Center has a fully-approved, free-standing OB-GYN Residency Program with two residents each year and trains a total of 70 residents and 400 medical students.

The hospital is a regional Level III Perinatal Center. Of over 3,000 births in 1990, 42 percent were in the high-risk category. The department is supported by a 20-bed Level III NICU managed by four full-time neonatologists.

In response to the continuing growth of the community and the expansion of the OB-GYN Department, the hospital will ask the new Chair to lead the search for the newly-created position of Vice Chair/Program Director of OB-GYN. The department is also awaiting the arrival of the new Chair to help in the search for a full-time perinatologist. (There are 33 active OB-GYN physicians on staff, including a gynecologic oncologist and reproductive endocrinologist.)

The hospital is a clinical campus of Hahnemann University in Philadelphia, where the new Chair will hold a Vice Chair appointment and an academic appointment at the rank of associate or full professor. The hospital is in Allentown, a burgeoning area in eastern Pennsylvania within close proximity of Philadelphia and New York City.

Candidates must be board certified with administrative experience and familiarity with both academic and community hospital environments. Interested candidates may write or call for information and send curricula vitae, in confidence, to: **Headley S. White, Jr., M.D., Sr. Vice President, Medical and Academic Affairs, c/o HealthSearch, 1243 S. Cedar Crest Blvd., Suite 3000, Allentown, PA 18103, (215) 821-3090.** Descriptive brochure available.

MATERNAL-FETAL MEDICINE
INDIANAPOLIS, INDIANA

POSITION OFFERS:

- Academics • Research • Private Practice

FACILITIES—METHODIST HOSPITAL OF INDIANA:

- 1,100 acute-care beds
- 5,000 deliveries per year
- Level III Nursery
- Pediatric ICU
- In-house OB/GYN residency program
- Research opportunities

COMPENSATION INCLUDES:

- Salary from Methodist Hospital
- Private practice income
- Total package of over $250,000 net the first year
- **Plus** generous benefits, including health, life, dental, disability, and malpractice insurance.

JACKSON AND COKER

FACULTY POSITIONS
GENERAL OBSTETRICS AND GYNECOLOGY

The University of North Carolina at Chapel Hill, Department of Obstetrics and Gynecology, in conjunction with the Wake Medical Center, Raleigh, North Carolina, and the Wake Area Health Education Center is seeking two board eligible or active candidates in General Obstetrics and Gynecology. One position will require special interest in gynecological surgery and the other special interest in obstetrics.

Wake Medical Center is located in Raleigh, the State Capitol, approximately 40 minutes from Chapel Hill, and is a 560-bed comprehensive tertiary care center with over 4000 deliveries and 1500 surgical procedures each year.

The positions are in the Wake AHEC OB/GYN Department which has four other full-time obstetricians and gynecologists.

Excellent opportunity for clinical research and teaching of the UNC/Chapel Hill Ob/Gyn residents and medical students rotating through Wake Medical Center at all times. Collaboration with the Department of Obstetrics and Gynecology at Chapel Hill is encouraged and anticipated.

Salary and academic rank commensurate with training and experience. Superb fringe benefits package.

The University of North Carolina is an Equal Opportunity/Affirmative Action Employer.

Virginia Baptist Hospital

3300 Rivermont Ave., Lynchburg, VA 24503-2053

Virginia Baptist Hospital is assisting our local staff of obstetricians in recruiting OB/GYN physicians to join established practices. Located in Lynchburg, Virginia at the foot of the Blue Ridge Mountains, Virginia Baptist Hospital is a full-service JCAHO accredited 387-bed hospital serving a population of 250,000. Annually deliveries average 2,400 supported by nine private practicing obstetricians, one perinatologist, and one hospital-based obstetrician with certified nurse midwives providing indigent care services. Virginia Baptist is the designated maternal/child center for this region; therefore, obstetrical practice is confined to this hospital which offers a wide spectrum of birthing options. Lynchburg is convenient to summer and winter resorts and boasts an excellent public school system as well a private schools and five colleges. Salary and benefits are excellent. To arrange a private interview, submit C.V. to Dianne T. Nash, Vice President, Virginia Baptist Hospital, 3300 Rivermont Avenue, Lynchburg, Virginia, 24503, or call (804) 947-4521, collect.

An Affirmative Action/Equal Opportunity Employer

PERINATOLOGIST

Outstanding practice opportunity for a BC/BE perinatologist to join an established practice at Iowa's largest private teaching medical center. The hospital, a state designated Level III Perinatal Center, averages over 2,000 deliveries annually and has an active maternal and neonatal transport system. The medical center's Level III Neonatal Intensive Care Unit is staffed by four board certified neonatologists. Complete laboratory facilities are available including cytogenic analysis of both amniotic fluid and trophoblastic tissue. The Antepartum Testing Unit is equipped with computer-based fetal monitors and a color flow Doppler ultrasound unit. Excellent financial and lifestyle opportunities are available to the qualified candidate. Please call 1-800-882-5911 or send CV to Mariann Clark, Medical Search Consultant, 1200 Pleasant Street, Des Moines, Iowa 50309.

OBSTETRICS & GYNECOLOGY

Obstetrician/Gynecologist needed to join a five physician department at a major regional multispecialty clinic in Billings, Montana. Clinic setting includes all specialties and is adjacent to an outstanding tertiary care referral hospital. Excellent opportunity for a top notch board eligible or board certified Obstetrican/Gynecologist looking for a challenging practice in a geographic area offering unlimited recreational potential. Those interested send CV to:

Ann B. Oglesby, M.B.A., M.D.
Medical Director
Billings Clinic
P.O. Box 35100
Billings, Montana 59107-5100

DIRECTOR OF MATERNAL-FETAL MEDICINE

Albert Einstein Medical Center (AEMC), a 600+ bed tertiary care teaching hospital, is seeking a board certified maternal-fetal medicine subspecialist as Director of the Division of Maternal-Fetal Medicine to develop and direct the comprehensive perinatal program in this institution. AEMC is a major referral center in north Philadelphia supporting numerous post-graduate medical education programs, including a fully accredited residency program in obstetrics and gynecology. The Department of Obstetrics and Gynecology has a long-standing tradition of excellence in health-care delivery and supports a variety of clinical research and educational activities. The Division of Maternal-Fetal Medicine serves as a tertiary referral center within the metropolitan Philadelphia area. Its service includes maternal intensive care unit, maternal transport program, high risk obstetrics, genetic counseling, diagnostic genetic procedures (amniocentesis, CVS, cordocentesis), targeted (level II) obstetrical ultrasound and comprehensive antenatal fetal surveillance. Our Department is supported by a Level III NICU and a Cytogenetic Laboratory. There is a strong institutional support and emphasis in research with funds and laboratory space available for basic research. A construction project is under way for a new labor and delivery suite and a comprehensive fetal diagnostic center. We are also planning to develop a maternal-fetal medicine fellowship training program with Temple University.

AEMC is a major affiliate of Temple University. Academic appointment is available for all full-time AEMC faculty. Highly competitive salary and very attractive fringe benefits are included. If you are interested in this position or would like additional information about this unique opportunity, please write to *Sze-ya Yeh, M.D., Chairman, Department of Obstetrics and Gynecology, Albert Einstein Medical Center, 5401 Old York Road, Klein #410, Philadelphia, PA 19141.* Telephone **(215) 456-6993,** FAX **(215) 456-6271.**

DIRECTOR, DIVISION OF MATERNAL FETAL MEDICINE

Director, Division of Maternal Fetal medicine at university medical center affiliate of Tufts University School of Medicine. This challenging position provides opportunity to lead Maternal Fetal Medicine Division of the Department of OB/GYN of St. Margaret's Hospital for Women and St. Elizabeth's Hospital of Boston at SEH campus. Successful candidate must qualify for senior level faculty appointment at Tufts, have experience in leadership of OB/GYN and Maternal Fetal Medicine residency education and research; and interest in medical student education. Competitive salary and benefits package available. Please forward curriculum vitae to:

James P. Durkan, M.D.
Chairman, Department of OB/GYN
St. Elizabeth's Hospital of Boston
736 Cambridge St.
Brighton, MA 02135

COLORADO

BC/BE female/male DO/MD sought to join progressive 2 man group. Association leading to early partnership with excellent income potential. Office located in one of Denver's fastest growing north west suburbs. Opportunity available immediately. Send inquiries and C.V. to:

A. E. Murray
Director, Medical Staff Services
8300 West 38th Avenue
Wheat Ridge, Colorado 80033

Obstetrician/ Gynecologists

Marshfield Clinic, a 350 physician multispecialty group practice is seeking BE/BC Obstsetrician/Gynecologists to join expanding regional referral centers in Chippewa Falls and Woodruff/Minocqua, Wisconsin. These are beautiful four-season recreational locations combining professional excellence with a family-oriented life style. Both have newly constructed Clinics with comparably modern hospitals. These practices provide an opportunity to enjoy the autonomy of a private practice with the financial and professional resources of a major multispecialty group. **Chippewa Falls** is located 1 1/2 hours from downtown Minneapolis/St. Paul and borders Eau Claire, Wisconsin, a city of nearly 80,000 which includes a major 4 year campus of the University of Wisconsin. Known as the "Lakeland Area," **Woodruff/Minocqua** is truly one of the most attractive vacation areas in the upper Midwest. An emphasis on quality practice and life style is combined with a very competitive salary and one of the finest fringe benefit packages in the country. For additional information, please send C.V. and references to: **David L. Draves, Director Regional Development, Marshfield Clinic**, 1000 North Oak Avenue, Marshfield, WI 54449, or call 1-800-826-2345, extension 5376.

CHIEF, OBSTETRICS/GYNECOLOGY

Newton-Wellesley Hospital, a 340-bed Tufts affiliated community teaching hospital, located less than 10 miles west of Boston, is conducting a search for a Chief to head the Department of Obstetrics & Gynecology. This position is full-time including practice opportunities.

Candidates must be board certified in Obstetrics and Gynecology and have strong clinical interests and skills, a commitment to family-centered patient care, management skills, and an ability to lead an active educational program geared to the needs of a rapidly growing department. Interest and expertise in one of the subspecialties of Obstetrics and Gynecology is preferred.

There are currently 3600 deliveries per year at the Newton-Wellesley Hospital, with continued growth anticipated. The Maternity Facility consists of a 20-bed LDRP Unit, 6 LDR suites, 2 C-section/high risk delivery suites, 2-bed PACU and 24-bed post partum unit, and an antenatal testing unit. This service is supported by a 12-bed, Level II, special care nursery, as well as full-time neonatology and anesthesia coverage.

The successful candidate will be responsible for the ongoing clinical, administrative, and teaching activities for the department, as well as for the direction of its active growth and development.

Interested candidates should forward their curriculum vitae to: Joel Rubenstein, M.D., Chairman, Search Committee, Newton-Wellesley Hospital, 2000 Washington Street, Newton, MA 02162.

The one drug test a woman can't afford to fail.

Knowing the right answers to this test can mean the difference between life and death to a woman and her unborn child. Cut it out now and give copies to all your patients, even if you don't suspect a drug problem. Even if they are not pregnant. Because if your patients don't know the right answers, now's the time to talk with them and help them to understand.

Drugs and Pregnancy: Did you know?

1. Did you know that if you use cocaine while you're pregnant, you have a much greater chance of having a miscarriage? ☐ YES ☐ NO

2. Did you know that if you use cocaine, you can pass it on to your baby through your breast milk? ☐ YES ☐ NO

3. Did you know that if you use any illicit drug while you're pregnant, there's a greater chance that you will have a low-birthweight baby? ☐ YES ☐ NO

4. Did you know that low birthweight is associated with a greater risk of infant death and mental and physical handicaps? ☐ YES ☐ NO

5. Did you know that heroin use during pregnancy increases the likelihood of stillbirth and death among newborns? ☐ YES ☐ NO

6. Did you know that if you or any of your sexual partners ever used an illicit IV drug, you may be infected with the AIDS virus (HIV), and that you can pass that virus on to your unborn child? ☐ YES ☐ NO

7. Did you know that if you use cocaine, are addicted to heroin, or are methadone-dependent, your children will be at a greater risk for sudden infant death syndrome (SIDS)? ☐ YES ☐ NO

8. Did you know that if you use barbiturates during your pregnancy you can change your child's normal patterns of growth and behavior? Your child might also suffer withdrawal symptoms for months after birth, including high-pitched crying, irritability, and sleep disturbances. ☐ YES ☐ NO

9. Is your doctor aware of all the prescription and/or illicit drugs you may be taking? ☐ YES ☐ NO

Did you know that if you have a drug problem, there are many people and resources you can turn to for help? Just ask your doctor. ☐ YES ☐ NO

✂ *Cut along dotted line, copy, and distribute to patients as you see fit.*

Obstetrics and Gynecology Review Course

October 21-26, 1991 – Chicago
†December 2-7, 1991 – Chicago

Now, your course for exams has practice tests and case-list reviews

OBJECTIVES

- Increase basic knowledge and clinical skills in ob-gyn
- Assist residents and fellows to organize their study
- Prepare exam candidates to take their examinations
- Provide practicing gynecologists with an update

METHODS

- HOME STUDY MATERIALS with questions and answers
- SEMINAR with projection slides and lecture-note syllabus
- LABORATORY with microscope and glass slides
- PRACTICE EXAMS with both oral and written sections

†Plus extra mock oral days December 8-9

*"The faculty was outstanding. The most pleasant thing was learning a tremendous amount, not only from world-famous authorities but from people who are relatively unknown as well."**

*"The course was extremely helpful to me."**

COURSES: This course is a comprehensive review and update given several times per year. Fall courses are more clinically oriented. Home study questions are sent upon registration. The course includes lectures with syllabus as well as an opportunity for you to buy an unlimited number of half-hour, one-on-one sessions with faculty to review your case lists or perform mock oral exams. The optional extra days, Dec. 8-9, include one mock oral exam and observation of seven or more hours of other exams. Past participants recommend repeating the course for half price immediately before exams.

*"Accommodations were comfortable...."**

LOCATIONS: The courses will be at the Hilton Inn, Lisle, Illinois. Our group rates are $85 single; $110 double.

*"...and those little extras...."**

DISCOUNT AIR FARES: Please call toll-free 1-800-548-8185 for group discounts.

*"...the most education for the money."**

FEES FOR 60 HOURS:

• Practicing Gynecologist:	$750
• Resident or Fellow:	$500
• Repeating course within 2 years:	$375
• Optional extra day Dec. 8 and 9 (more questions, answers and pathology lab):	$150

- **Add 10% within 10 days of the course.**
- Attendees not in course hotel add $20/day.
- A deposit of $50 will reserve your position.
- Most home study materials will be mailed after half of the registration fee is received.

*"...home study material was extremely helpful."**

REFUNDS: Subject to a $50 fee, refunds will be made until the seminar begins.

*"...remarkably complete and pleasant."**

21- and 28-day regimens

RTHO-NOVUM® 777 Tablets

ethindrone/ethinyl estradiol

Low incidence of androgenic side effects

h white tablet contains 0.5 mg norethindrone and 0.035 mg ethinyl estradiol. Each light peach tablet tains 0.75 mg norethindrone and 0.035 mg ethinyl estradiol. Each peach tablet contains 1 mg noreth- rone and 0.035 mg ethinyl estradiol. Each green tablet in 28-day regimen contains inert ingredients.

PORTANT NOTE—This information is a BRIEF SUMMARY of the complete prescribing information vided with the product and therefore should not be used as the basis for prescribing the product. s summary was prepared by deleting from the complete prescribing information certain text, tables l references. The physician should be thoroughly familiar with the complete prescribing information ore prescribing the product.

ICATIONS AND USAGE: PREVENTION OF PREGNANCY.

NTRAINDICATIONS: Oral contraceptives should not be used in women who currently have the following ditions: 1. Thrombophlebitis or thromboembolic disorders. 2. A past history of deep vein thrombophle- s or thromboembolic disorders. 3. Cerebral vascular or coronary artery disease. 4. Known or suspected cinoma of the breast. 5. Carcinoma of the endometrium or other known or suspected estrogen-depen- t neoplasia. 6. Undiagnosed abnormal genital bleeding. 7. Cholestatic jaundice of pregnancy or jaundice h prior pill use. 8. Hepatic adenomas or carcinomas. 9. Known or suspected pregnancy.

WARNINGS

igarette smoking increases the risk of serious cardiovascular side effects from oral contracep- ive use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and s quite marked in women over 35 years of age. Women who use oral contraceptives should be trongly advised not to smoke.

use of oral contraceptives is associated with increased risks of several serious conditions including ocardial infarction, thromboembolism, stroke, hepatic neoplasia, and gallbladder disease, although the of serious morbidity or mortality is very small in healthy women without underlying risk factors. The of morbidity and mortality increases significantly in the presence of other underlying risk factors such hypertension, hyperlipidemias, obesity and diabetes. Practitioners prescribing oral contraceptives uld be familiar with the following information relating to these risks. The information contained in this f summary is principally based on studies carried out in patients who used oral contraceptives with her formulations of estrogens and progestogens than those in common use today. The effect of long m use of the oral contraceptives with lower formulations of both estrogens and progestogens remains be determined. Throughout this brief summary epidemiological studies reported are of two types: ospective or case control studies and prospective or cohort studies. Case control studies provide a asure of the relative risk of a disease, namely a *ratio* of the incidence of a disease among oral contra- tive users to that among nonusers. The relative risk does not provide information on the actual clinical urrence of a disease. Cohort studies provide a measure of attributable risk, which is the *difference* in incidence of disease between oral contraceptive users and nonusers. The attributable risk does pro- e information about the actual occurrence of a disease in the population. For further information, the der is referred to a text on epidemiological methods. 1. THROMBOEMBOLIC DISORDERS AND OTHER SCULAR PROBLEMS. a. Myocardial Infarction. An increased risk of myocardial infarction has been ociated with oral contraceptive use. This risk is primarily in smokers or women with other underlying factors for coronary artery disease such as hypertension, hypercholesterolemia, morbid obesity, and etes. The relative risk of heart attack for current oral contraceptive users has been estimated to be two six. The risk is very low under the age of 30. Smoking in combination with oral contraceptive use has n shown to contribute substantially to the incidence of myocardial infarctions in women in their -thirties or older with smoking accounting for the majority of excess cases. Mortality rates associated h circulatory disease have been shown to increase substantially in smokers, especially in those 35 rs of age and older among women who use oral contraceptives. Oral contraceptives may compound the cts of well-known risk factors, such as hypertension, diabetes, hyperlipidemias, age and obesity. In ticular, some progestogens are known to decrease HDL cholesterol and cause glucose intolerance, le estrogens may create a state of hyperinsulinism. Oral contraceptives have been shown to increase od pressure among users (see section 9 in WARNINGS). Similar effects on risk factors have been ociated with an increased risk of heart disease. Oral contraceptives must be used with caution in nen with cardiovascular disease risk factors. b. Thromboembolism. An increased risk of thromboem- c and thrombotic disease associated with the use of oral contraceptives is well established. Case trol studies have found the relative risk of users compared to non-users to be 3 for the first episode of erficial venous thrombosis, 4 to 11 for deep vein thrombosis or pulmonary embolism, and 1.5 to 6 for nen with predisposing conditions for venous thromboembolic disease. Cohort studies have shown the tive risk to be somewhat lower, about 3 for new cases and about 4.5 for new cases requiring hospital- ion. The risk of thromboembolic disease associated with oral contraceptives is not related to length of and disappears after pill use is stopped. A two- to four-fold increase in relative risk of post-operative mboembolic complications has been reported with the use of oral contraceptives. The relative risk of ous thrombosis in women who have predisposing conditions is twice that of women without such lical conditions. If feasible, oral contraceptives should be discontinued at least four weeks prior to and two weeks after elective surgery of a type associated with an increase in risk of thromboembolism and ing and following prolonged immobilization. Since the immediate postpartum period is also associated an increased risk of thromboembolism, oral contraceptives should be started no earlier than four ks after delivery in women who elect not to breast feed. c. Cerebrovascular diseases. Oral contracep- s have been shown to increase both the relative and attributable risks of cerebrovascular events ombotic and hemorrhagic strokes), although, in general, the risk is greatest among older (>35 years), ertensive women who also smoke. Hypertension was found to be a risk factor for both users and -users, for both types of strokes, and smoking interacted to increase the risk of stroke. In a large study, relative risk of thrombotic strokes has been shown to range from 3 for normotensive users to 14 for rs with severe hypertension. The relative risk of hemorrhagic stroke is reported to be 1.2 for non- kers who used oral contraceptives, 2.6 for smokers who did not use oral contraceptives, 7.6 for kers who used oral contraceptives, 1.8 for normotensive users and 25.7 for users with severe hyper- sion. The attributable risk is also greater in older women. d. Dose-related risk of vascular disease from contraceptives. A positive association has been observed between the amount of estrogen and gestogen in oral contraceptives and the risk of vascular disease. A decline in serum high density proteins (HDL) has been reported with many progestational agents. A decline in serum high density proteins has been associated with an increased incidence of ischemic heart disease. Because estro- s increase HDL cholesterol, the net effect of an oral contraceptive depends on a balance achieved ween doses of estrogen and progestogen and the activity of the progestogen used in the contraceptive. activity and amount of both hormones should be considered in the choice of an oral contraceptive. imizing exposure to estrogen and progestogen is in keeping with good principles of therapeutics. For particular estrogen/progestogen combination, the dosage regimen prescribed should be one which tains the least amount of estrogen and progestogen that is compatible with a low failure rate and the ds of the individual patient. New acceptors of oral contraceptive agents should be started on prepara- s containing 0.035 mg or less of estrogen. e. Persistence of risk of vascular disease. There are two lies which have shown persistence of risk of vascular disease for ever-users of oral contraceptives. In a ly in the United States, the risk of developing myocardial infarction after discontinuing oral contracep- s persists for at least 9 years for women 40-49 years who had used oral contraceptives for five or e years, but this increased risk was not demonstrated in other age groups. In another study in Great ain, the risk of developing cerebrovascular disease persisted for at least 6 years after discontinuation ral contraceptives, although excess risk was very small. However, both studies were performed with contraceptive formulations containing 50 micrograms or higher of estrogens. 2. ESTIMATES OF RTALITY FROM CONTRACEPTIVE USE. One study gathered data from a variety of sources which have mated the mortality rate associated with different methods of contraception at different ages. These mates include the combined risk of death associated with contraceptive methods plus the risk attribu- e to pregnancy in the event of method failure. Each method of contraception has its specific benefits risks. The study concluded that with the exception of oral contraceptive users 35 and older who smoke 40 and older who do not smoke, mortality associated with all methods of birth control is low and w that associated with childbirth. However, smokers 35 and older and non-smokers 40 and older who oral contraceptives have a significant increase in mortality higher than those using other methods of control. These facts must be weighed in conjunction with failure rates for other methods and the risk ciated with subsequent pregnancy. 3. CARCINOMA OF THE REPRODUCTIVE ORGANS. Numerous emiological studies have been performed on the incidence of breast, endometrial, ovarian and cervical er in women using oral contraceptives. While there are conflicting reports most studies suggest that of oral contraceptives is not associated with an overall increase in the risk of developing breast cancer. e studies have reported an increased relative risk of developing breast cancer, particularly at a ger age. This increased relative risk appears to be related to duration of use. Some studies suggest that oral contraceptive use has been associated with an increase in the risk of cervical intraepithelial neoplasia in some populations of women. However, there continues to be controversy about the extent to which such findings may be due to differences in sexual behavior and other factors. 4. HEPATIC NEOPLASIA. Benign hepatic adenomas are associated with oral contraceptive use, although the incidence of benign tumors is rare in the United States. Indirect calculations have estimated the attributable risk to be in the range of 3.3 cases/100,000 for users, a risk that increases after four or more years of use especially with oral contraceptives of higher dose. Rupture of benign, hepatic adenomas may cause death through intra-abdominal hemorrhage. Studies from Britain have shown an increased risk of developing hepatocellular carcinoma in long-term (>8 years) oral contraceptive users. However, these cancers are rare in the U.S. and the attributable risk (the excess incidence) of liver cancers in oral contraceptive users approaches less than one per million users. 5. OCULAR LESIONS. There have been clinical case reports of retinal thrombosis associated with the use of oral contraceptives. Oral contraceptives should be discontinued if there is unexplained partial or complete loss of vision; onset of proptosis or diplopia, papilledema, or retinal vascular lesions. Appropriate diagnostic and therapeutic measures should be undertaken immediately. 6. ORAL CONTRACEPTIVE USE BEFORE OR DURING EARLY PREGNANCY. Extensive epidemiological studies have revealed no increased risk of birth defects in women who have used oral contraceptives prior to pregnancy. The majority of recent studies also do not indicate a teratogenic effect, particularly in so far as cardiac anomalies and limb reduction defects are concerned, when taken inadvertently during early pregnancy. The administration of oral contraceptives to induce withdrawal bleeding should not be used as a test for pregnancy. Oral contraceptives should not be used during pregnancy to treat threatened or habitual abortion. It is recommended that for any patient who has missed two consecutive periods pregnancy should be ruled out before continuing oral contraceptive use. If the patient has not adhered to the prescribed schedule, the possibility of pregnancy should be considered at the time of the first missed period. Oral contraceptive use should be discontinued until pregnancy is ruled out. 7. GALLBLADDER DISEASE. Earlier studies have reported an increased lifetime relative risk of gallbladder surgery in users of oral contraceptives and estrogens. More recent studies, however, have shown that the relative risk of developing gallbladder disease among oral contraceptive users may be minimal. The recent findings of minimal risk may be related to the use of oral contraceptive formulations containing lower hormonal doses of estrogens and progestogens. 8. CARBOHYDRATE AND LIPID METABOLIC EFFECTS. Oral contraceptives have been shown to cause a decrease in glucose tolerance in a significant percentage of users. This effect has been shown to be directly related to estrogen dose. Progestogens increase insulin secretion and create insulin resistance, this effect varying with different progestational agents. However, in the non-diabetic woman, oral contraceptives appear to have no effect on fasting blood glucose. Because of these demonstrated effects prediabetic and diabetic women in particular should be carefully monitored while taking oral contraceptives. A small proportion of women will have persistent hypertriglyceridemia while on the pill. As discussed earlier (see WARNINGS 1a and 1d), changes in serum triglycerides and lipoprotein levels have been reported in oral contraceptive users. 9. ELEVATED BLOOD PRESSURE. An increase in blood pressure has been reported in women taking oral contraceptives, and this increase is more likely in older oral contraceptive users and with extended duration of use. Data from the Royal College of General Practitioners and subsequent randomized trials have shown that the incidence of hypertension increases with increasing progestational activity. Women with a history of hypertension or hypertension-related diseases, or renal disease, should be encouraged to use another method of contraception. If women elect to use oral contraceptives, they should be monitored closely and if significant elevation of blood pressure occurs, oral contraceptives should be discontinued. For most women, elevated blood pressure will return to normal after stopping oral contraceptives, and there is no difference in the occurrence of hypertension between former and never users. 10. HEADACHE. The onset or exacerbation of migraine or development of headache with a new pattern which is recurrent, persistent or severe requires discontinuation of oral contraceptives and evaluation of the cause. 11. BLEEDING IRREGULARITIES. Breakthrough bleeding and spotting are sometimes encountered in patients on oral contraceptives, especially during the first three months of use. Non-hormonal causes should be considered and adequate diagnostic measures taken to rule out malignancy or pregnancy in the event of breakthrough bleeding as in the case of any abnormal vaginal bleeding. If pathology has been excluded, time or a change to another formulation may solve the problem. In the event of amenorrhea, pregnancy should be ruled out. Some women may encounter post-pill amenorrhea or oligomenorrhea, especially when such a condition was preexistent. 12. ECTOPIC PREGNANCY. Ectopic as well as intrauterine pregnancy may occur in contraceptive failures. **PRECAUTIONS:** 1. PHYSICAL EXAMINATION AND FOLLOW UP. A complete medical history and physical examination should be taken prior to the initiation or reinstitution of oral contraceptives and at least annually during use of oral contraceptives. These physical examinations should include special reference to blood pressure, breasts, abdomen and pelvic organs, including cervical cytology, and relevant laboratory tests. In case of undiagnosed persistent or recurrent abnormal vaginal bleeding, appropriate diagnostic measures should be conducted to rule out malignancy. Women with a strong family history of breast cancer or who have breast nodules should be monitored with particular care. 2. LIPID DISORDERS. Women who are being treated for hyperlipidemias should be followed closely if they elect to use oral contraceptives. Some progestogens may elevate LDL levels and may render the control of hyperlipidemias more difficult. 3. LIVER FUNCTION. If jaundice develops in any woman receiving such drugs, the medication should be discontinued. Steroid hormones may be poorly metabolized in patients with impaired liver function. 4. FLUID RETENTION. Oral contraceptives may cause some degree of fluid retention. They should be prescribed with caution, and only with careful monitoring, in patients with conditions which might be aggravated by fluid retention. 5. EMOTIONAL DISORDERS. Women with a history of depression should be carefully observed and the drug discontinued if depression recurs to a serious degree. 6. CONTACT LENSES. Contact lens wearers who develop visual changes or changes in lens tolerance should be assessed by an ophthalmologist. 7. DRUG INTERACTIONS. Reduced efficacy and increased incidence of breakthrough bleeding and menstrual irregularities have been associated with concomitant use of rifampin. A similar association, though less marked, has been suggested with barbiturates, phenylbutazone, phenytoin sodium, and possibly with griseofulvin, ampicillin and tetracyclines. 8. INTERACTIONS WITH LABORATORY TESTS. Certain endocrine and liver function tests and blood components may be affected by oral contraceptives: a. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3, increased norepinephrine-induced platelet aggregability. b. Increased thyroid binding globulin (TBG) leading to increased circulating total thyroid hormone, as measured by protein-bound iodine (PBI), T4 by column or by radio-immunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG, free T4 concentration is unaltered. c. Other binding proteins may be elevated in serum. d. Sex-binding globulins are increased and result in elevated levels of total circulating sex steroids and corticoids; however, free or biologically active levels remain unchanged. e. Triglycerides may be increased. f. Glucose tolerance may be decreased. g. Serum folate levels may be depressed by oral contraceptive therapy. This may be of clinical significance if a woman becomes pregnant shortly after discontinuing oral contraceptives. 9. CARCINOGENESIS. See WARNINGS section. 10. PREGNANCY. Pregnancy Category X. See CONTRAINDICATIONS and WARNINGS sections. 11. NURSING MOTHERS. Small amounts of oral contraceptive steroids have been identified in the milk of nursing mothers and a few adverse effects on the child have been reported, including jaundice and breast enlargement. In addition, oral contraceptives given in the postpartum period may interfere with lactation by decreasing the quantity and quality of breast milk. If possible, the nursing mother should be advised not to use oral contraceptives but to use other forms of contraception until she has completely weaned her child. **INFORMATION FOR THE PATIENT: See Patient Package Insert.** **ADVERSE REACTIONS:** An increased risk of the following serious adverse reactions has been associated with the use of oral contraceptives (see WARNINGS section). Thrombophlebitis and venous thrombosis with or without embolism. Arterial thromboembolism. Pulmonary embolism. Myocardial infarction. Cerebral hemorrhage. Cerebral thrombosis. Hypertension. Gallbladder disease. Hepatic adenomas or benign liver tumors. The following adverse reactions have been reported in patients receiving oral contraceptives and are believed to be drug-related: Nausea. Vomiting. Gastrointestinal symptoms (such as abdominal cramps and bloating). Breakthrough bleeding. Spotting. Change in menstrual flow. Amenorrhea. Temporary infertility after discontinuation of treatment. Edema. Melasma which may persist. Breast changes: tenderness, enlargement, secretion. Change in weight (increase or decrease). Change in cervical erosion and secretion. Diminution in lactation when given immediately postpartum. Cholestatic jaundice. Migraine. Rash (allergic). Mental depression. Reduced tolerance to carbohydrates. Vaginal candidiasis. Change in corneal curvature (steepening). Intolerance to contact lenses. The following adverse reactions have been reported in users of oral contraceptives and the association has been neither confirmed nor refuted: Pre-menstrual syndrome. Cataracts. Changes in appetite. Cystitis-like syndrome. Headache. Nervousness. Dizziness. Hirsutism. Loss of scalp hair. Erythema multiforme. Erythema nodosum. Hemorrhagic eruption. Vaginitis. Porphyria. Impaired renal function. Hemolytic uremic syndrome. Acne. Changes in libido. Colitis. **OVERDOSAGE:** Serious ill effects have not been reported following acute ingestion of large doses of oral contraceptives by young children. Overdosage may cause nausea and withdrawal bleeding may occur in females.

Outstanding Clinical Performance Reflected Inside & Outside

13 DEC 1991

INSIDE

Low Metabolic Impact is reflected inside your ORTHO-NOVUM[*] 7/7/7 patients[†]: No clinically significant change in plasma glucose and insulin levels in nondiabetic women.[‡,1] Mean values for total cholesterol, HDL or LDL, and blood pressure also show no significant change.[§]

Excellent Cycle Control is another reflection of outstanding performance with ORTHO-NOVUM 7/7/7. You can expect low discontinuation rates due to breakthrough bleeding, spotting, and amenorrhea.

OUTSIDE

Low Incidence of Androgenic Side Effects—such as acne, oily skin, or hirsutism—is a visible reflection that your patients may notice; another is no clinically significant change in mean body weight. Inside and outside, the outstanding performance of ORTHO-NOVUM 7/7/7 is also an excellent reflection on you.

Low incidence of androgenic side effects

21- and 28-day regimens

[†] Serious as well as minor side effects have been reported with the use of oral contraceptives. The physician should remain alert to the earliest manifestations of any symptoms of serious disease and discontinue oral contraceptive therapy when appropriate.

[‡] Oral contraceptives have been shown to cause a decrease in glucose tolerance in a significant percentage of users. Progestogens increase insulin secretion and create insulin resistance, this effect varying with different progestational agents.

[§] An increase in blood pressure has been reported in women taking oral contraceptives.

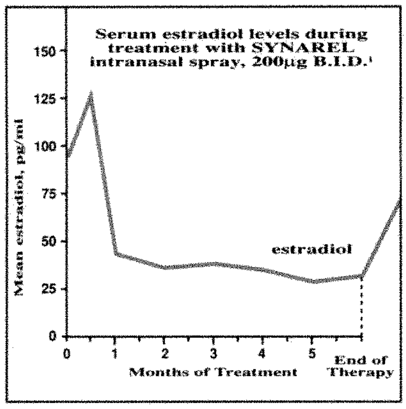
OF ENDOMETRIOSIS

enough is enough

Insufficient estradiol suppression may not resolve the symptoms of endometriosis. Excessive suppression may create additional problems for your patients.
SYNAREL intranasal spray promises no less than you need – and no more than you want.

Power to suppress estradiol to levels that result in effective relief

SYNAREL intranasal spray, 200μg B.I.D., lowers serum estradiol to near menopausal levels within approximately 1 month—and maintains those levels throughout the 6-month course of therapy.* As a result, 92% of patients (n=143) taking SYNAREL were symptom-free or had only mild symptoms following a 6-month course of therapy. And, of the 60% of patients (n=110) who had complete relief of symptoms, 83% remained symptom-free or experienced only mild symptoms 6 months after treatment with SYNAREL was discontinued. Retreatment cannot be recommended since safety data for retreatment are not currently available.



Control in the management of hypoestrogenic and therapeutic effects

SYNAREL produces minimal impact on bone, as well as a predictable and manageable hypoestrogenic profile. What's more, SYNAREL lets you terminate treatment immediately should that be required for any reason—unlike the depot form of GnRH[†] therapy. In fact, drug clearance with SYNAREL usually occurs within 24 hours.[2]

Bone density changes during and after treatment with SYNAREL intranasal spray, 400 μg/day [Percent changes from baseline]

Site Method Units	Time of Study Baseline	End of Treatment	Post-treatment
Lumbar Vertebrae QCT* Integral (g/vertebrae) n=21	13.4	12.8 –4.3%	13.1 –3.3%
Trabecular Bone of Vertebrae QCT* (mg/cc) n=23	161.3	147.6 –8.7%	152.0 –4.9%
Lumbar Vertebrae DPA† (g/cm²) n=6	0.98	0.93 –5.9%	0.96 –1.4%
Distal Radius SPA‡ (Units) n=6	40.2	39.5 –1.6%	39.6 –0.8%

*Quantitative computed tomography ‡Single photon absorptiometry
†Dual photon absorptiometry

SYNAREL is also well tolerated, with a low incidence of nasal irritation (10%). And, since SYNAREL lowers estrogen without adding androgens, it helps you avoid potentially irreversible androgenic effects. (The most frequent side effects are those associated with hypoestrogenism.)

In the management of endometriosis, only SYNAREL can balance the power you need with the control you want in a unique intranasal spray. For more information, please call 1-800-727-0400.

*Pregnancy should be ruled out before therapy with SYNAREL is initiated, and patients should be advised to use a nonhormonal method of contraception when taking SYNAREL.
†Gonadotropin-releasing hormone analog.

BRIEF SUMMARY

SYNAREL® Nasal Solution contains nafarelin acetate (2 mg/mL, expressed as nafarelin base), benzalkonium chloride, glacial acetic acid, sodium hydroxide or hydrochloric acid, sorbitol, and purified water.
INDICATIONS AND USAGE: For management of endometriosis. Experience is limited to women 18 years and older treated for 6 months.
CONTRAINDICATIONS: Hypersensitivity to GnRH, GnRH agonist analogs or any excipients in SYNAREL; undiagnosed abnormal vaginal bleeding; pregnancy or possibility of pregnancy while taking the drug because SYNAREL may cause fetal harm when administered to a pregnant woman. If SYNAREL is used during pregnancy or if the patient becomes pregnant while taking this drug, she should be apprised of the potential hazard to the fetus; use in women who are breast feeding.
WARNINGS: Safe use in pregnancy has not been established clinically. Before starting treatment pregnancy must be excluded.
When used regularly at the recommended dose, SYNAREL usually inhibits ovulation and stops menstruation. Contraception is not insured, particularly if patients miss successive doses. Therefore, patients should use nonhormonal contraception. Advise patients to see their physician if they believe they may be pregnant. If a patient becomes pregnant during treatment, discontinue the drug; apprise patient of the potential risk to the fetus.
PRECAUTIONS General: Ovarian cysts have been reported in the first 2 months of therapy. These may resolve spontaneously or may require drug discontinuation or surgery.
Information for Patients: 1. Since menstruation should stop with SYNAREL, the patient should notify her physician if regular menstruation persists. If patient is compliant and menstruation persists to second month, consider doubling the dose. Counsel noncompliant patients on importance of taking SYNAREL regularly. 2. Patients should not use SYNAREL if pregnant, breast feeding, have undiagnosed abnormal vaginal bleeding, or are allergic to any of its ingredients. 3. Safe use in pregnancy has not been established. Therefore, a nonhormonal method of contraception should be used during treatment. If a patient becomes pregnant during treatment, she should discontinue the drug and consult her physician. 4. Adverse events occurring most frequently in clinical studies are associated with hypoestrogenism. Nasal irritation occurred in about 10% of patients. 5. Induced hypoestrogenic state results in a small loss in bone density over a 6-month treatment course. Some of this loss may not be reversible. During one six-month treatment period, this should not be important. In patients with major risk factors for decreased bone mineral content, i.e., chronic alcohol and/or tobacco use, strong family history of osteoporosis, or chronic use of drugs that can reduce bone mass such as anticonvulsants or corticosteroids, SYNAREL may pose additional risk. In these patients risks and benefits must be weighed carefully. Repeated courses of treatment with GnRH analogs are not advisable in patients with major risk factors for loss of bone mineral content. 6. Patients with intercurrent rhinitis should consult their physician for use of a topical nasal decongestant. If a topical nasal decongestant is required during treatment, it must be used at least 30 minutes after SYNAREL dosing to decrease the possibility of reducing drug absorption. 7. Retreatment cannot be recommended since safety data beyond 6 months are not available.
Drug Interactions: No pharmacokinetic-based drug-drug interaction studies have been conducted. Nafarelin acetate is a peptide primarily degraded by peptidase and not by cytochrome P-450 enzymes, and is only about 80% bound to plasma proteins at 4°C; therefore drug interactions would not be expected to occur.
Drug/Laboratory Test Interactions: SYNAREL in therapeutic doses suppresses the pituitary-gonadal system. Normal function is usually restored 4-8 weeks after treatment is discontinued. Therefore, diagnostic tests of pituitary gonadotropic and gonadal functions during treatment and up to 4-8 weeks after discontinuation of SYNAREL may be misleading.
Carcinogenesis, Mutagenesis, Impairment of Fertility: Carcinogenicity studies were conducted in rats and mice at intramuscular doses up to 110 times and 560 times the maximum recommended human intranasal dose, respectively. These multiples of the human dose are based on the relative bioavailability of the drug by the two routes of administration. As with other GnRH agonists, nafarelin acetate given to laboratory rodents at high doses for prolonged periods induced hyperplasia and/or neoplasia of endocrine organs. At 24 months, there was an increase in the incidence of pituitary tumors (adenoma/carcinoma) in high-dose female rats and a dose-related increase in male rats. There was an increase in pancreatic islet cell adenomas in both sexes, and in benign testicular and ovarian tumors in the treated groups. There was a dose-related increase in benign adrenal medullary tumors in treated female rats. In mice, there was a dose-related increase in Harderian gland tumors in males and an increase in pituitary adenomas in high-dose females. No metastases of these tumors were observed. It is known that tumorigenicity in rodents is particularly sensitive to hormonal stimulation.

Mutagenicity studies using bacterial, yeast, and mammalian systems provided no evidence of mutagenic potential.

Reproduction studies in male and female rats have shown full reversibility of fertility suppression when treatment was discontinued after continuous administration for up to 6 months.
Pregnancy, Teratogenic Effects: *Pregnancy Category X.* Intramuscular SYNAREL was administered to rats throughout gestation at about 0.5, 2, and 7 times the maximum recommended human intranasal dose based on the relative bioavailability by the two routes of administration. An increase in major fetal abnormalities was seen in 4/80 fetuses at the highest dose. A similar study at the same doses in rats and studies in mice and rabbits at doses up to 600 μg/kg/day and 0.18 μg/kg/day, respectively, failed to demonstrate an increase in fetal abnormalities after administration throughout gestation. In rats and rabbits, there was a dose-related increase in fetal mortality and a decrease in fetal weight with the highest dose.
Nursing Mothers: It is not known whether SYNAREL is excreted in human milk. Because many drugs are excreted in human milk, and because the effects of SYNAREL on lactation and/or the breastfed child have not been determined, SYNAREL should not be used by nursing mothers.
Pediatric Use: Safety and effectiveness in children have not been established.
ADVERSE REACTIONS: The most frequently reported adverse reactions were those related to hypoestrogenism. In controlled studies comparing SYNAREL (400 μg/day) and danazol (600 or 800 mg/day), the following adverse reactions were most frequently reported and thought to be drug-related.
Hypoestrogenic: hot flashes (SYNAREL 90%, danazol 69%), decreased libido (22%, 7%), vaginal dryness (19%, 7%), headaches (19%, 21%), emotional lability (15%, 18%), insomnia (8%, 4%); **Androgenic:** acne (13%, 20%), myalgia (10%, 23%), reduced breast size (10%, 16%), edema (8%, 23%), seborrhea (8%, 17%), weight gain (8%, 28%), hirsutism (2%, 6%), increased libido (1%, 6%); **Local:** nasal irritation (10%, 3%); **Miscellaneous:** depression (2%, 5%), weight loss (1%, 3%).

Less than 1% of patients experienced paresthesia, palpitations, chloasma, maculopapular rash, eye pain, urticaria, asthenia, lactation, breast engorgement, and arthralgia. In clinical trials, immediate hypersensitivity thought to be possibly or probably related to nafarelin occurred in 3 (0.2%) of 1509 healthy subjects or patients.
Changes in Bone Density: After 6 months' treatment vertebral trabecular bone density and total vertebral bone mass, measured by quantitative computed tomography (QCT), decreased by an average of 8.7% and 4.3%, respectively, compared to pretreatment levels. There was partial recovery of bone density post-treatment; the average trabecular bone density and total bone mass were 4.9% and 3.3% less than pretreatment levels, respectively. Total vertebral bone mass, measured by dual photon absorptiometry (DPA), decreased by a mean of 5.9% at end of treatment. Mean total vertebral mass, re-examined by DPA 6 months post-treatment, was 1.4% below pretreatment levels. There was little, if any, decrease in the mineral content in compact bone of the distal radius and second metacarpal. Use for longer than the recommended 6 months or in presence of other known risk factors for decreased bone mineral content may cause additional bone loss.
Changes in Laboratory Values: *Plasma enzymes.* During clinical trials SGOT and SGPT levels were more than twice the upper limit of normal in only one patient each. There was no other evidence of abnormal liver function and levels returned to normal after treatment was stopped.
Lipids. At enrollment and at end of treatment, 9% of patients on SYNAREL 400 μg/day and 2% on danazol had total cholesterol values above 250 mg/dL.

Of those with pretreatment cholesterol values below 250 mg/dL, 6% on SYNAREL and 18% on danazol had post-treatment values above 250 mg/dL.

Mean (± SEM) pretreatment values for total cholesterol from all patients were 191.8 (4.3) mg/dL in the SYNAREL group and 193.1 (4.6) mg/dL in the danazol group. At the end of treatment, mean values from all patients were 204.5 (4.8) mg/dL in the SYNAREL group and 207.7 (5.1) mg/dL in the danazol group. These increases from pretreatment values were significant ($p < 0.05$) in both groups.

Triglycerides were increased above the upper limit of 150 mg/dL in 12% of the patients on SYNAREL and in 7% of the patients on danazol.

At the end of treatment, no patients on SYNAREL had abnormally low HDL cholesterol fractions (< 30 mg/dL) compared with 43% of patients on danazol. No patients on SYNAREL had abnormally high LDL cholesterol fractions (> 190 mg/dL) compared with 15% of those on danazol. There was no increase in the LDL/HDL ratio in patients on SYNAREL, but approximately a 2-fold increase in the LDL/HDL ratio in patients on danazol.
Other changes. In comparative studies, the following changes were seen in approximately 10% to 15% of patients. SYNAREL was associated with elevations of plasma phosphorous and eosinophil counts, and decreases in serum calcium and WBC counts. Danazol therapy was associated with an increase of hematocrit and WBC.
OVERDOSAGE: At present there is no clinical evidence of adverse effects following overdosage of GnRH analogs.

GYNECOLOGIC ONCOLOGIS

Albert Einstein Medical Center (AEMC), a 600+
tertiary care teaching hospital, is seeking a gyneco
oncologist to establish a service in the Divisio
Gynecologic Oncology. AEMC is a major referral ce
in north Philadelphia supporting numerous post-grad
medical education programs, including a fully accre
residency program in obstetrics and gynecology.
Department of Obstetrics and Gynecology has a l
standing tradition of excellence in healthcare deli
and supports a variety of clinical research and ed
tional activities. The Division of Gynecologic Oncc
serves as a tertiary referral center within the metropc
Philadelphia area. This service is supported by a st
Department of Radiation Oncology and a newly e
lished Cancer Center with a state of the art facilit
outpatient chemotherapy. There is also major instituti
support and emphasis in research with funds and lab
tory space available for basic research. The res
sibilities include education, patient care and resear

Triphasil®

Levonorgestrel and ethinyl estradiol tablets—
Triphasic regimen 21- and 28-day regimens

THE OC TO START WITH BECAUSE SHE'LL STAY WITH IT

IN BRIEF:
TRIPHASIL® — 6 brown tablets containing 0.050 mg levonorgestrel with 0.030 mg ethinyl estradiol; 5 white tablets containing 0.075 mg levonorgestrel with 0.040 mg ethinyl estradiol; 10 light-yellow tablets containing 0.125 mg levonorgestrel with 0.030 mg ethinyl estradiol (7 light-green tablets containing inert ingredients are included in the 28-day regimen) — Triphasic regimen.

Indications and Usage — TRIPHASIL® is indicated for the prevention of pregnancy in women who elect to use oral contraceptives (OC's) as a method of contraception.

Contraindications — OC's should not be used in women with any of the following conditions: 1. Thrombophlebitis or thromboembolic disorders. 2. A past history of deep-vein thrombophlebitis or thromboembolic disorders. 3. Cerebral-vascular or coronary-artery disease. 4. Known or suspected carcinoma of the breast. 5. Known or suspected estrogen-dependent neoplasia. 6. Undiagnosed abnormal genital bleeding. 7. Known or suspected pregnancy (see Warning No. 5) 8. Benign or malignant liver tumor which developed during use of OC's or other estrogen-containing products.

Warnings

Cigarette smoking increases the risk of serious cardiovascular side effects from oral contraceptive use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use oral contraceptives should be strongly advised not to smoke.
The use of oral contraceptives is associated with increased risk of several serious conditions, including thromboembolism, stroke, myocardial infarction, hepatic adenoma, gallbladder disease, hypertension. Practitioners prescribing oral contraceptives should be familiar with the following information relating to these risks.

1. *Thromboembolic Disorders and Other Vascular Problems* — An increased risk of thromboembolic and thrombotic disease associated with use of OC's is well established. Three principal studies in Great Britain and 3 in the U.S. have demonstrated increased risk of fatal and nonfatal venous thromboembolism and stroke, both hemorrhagic and thrombotic. These studies estimate that users of OC's are 4 to 11 times more likely than nonusers to develop these diseases without evident cause.

CEREBROVASCULAR DISORDERS — In a collaborative American study of cerebrovascular disorders in women with and without predisposing causes, it was estimated that the risk of hemorrhagic stroke was 2.0 times greater in users than nonusers and the risk of thrombotic stroke was 4 to 9.5 times greater in users than in nonusers.

MYOCARDIAL INFARCTION (MI) — An increased risk of MI associated with the use of OC's has been reported, confirming a previously suspected association. These studies, conducted in the UK, found, as expected, that the greater the number of underlying risk factors for coronary-artery disease (cigarette smoking, hypertension, hypercholesterolemia, obesity, diabetes, history of pre-eclamptic toxemia) the higher the risk of developing MI, regardless of whether the patient was an OC user or not. OC's, however, were found to be a clear additional risk factor. In terms of relative risk, it has been estimated that OC users who do not smoke (smoking is considered a major predisposing condition to MI) are about twice as likely to have a fatal MI as nonusers who do not smoke. OC users who are also smokers have about a 5-fold increased risk of fatal MI compared to users who do not smoke, but about a 10- to 12-fold increased risk compared to nonusers who do not smoke. Furthermore, amount of smoking is also an important factor. In determining importance of these relative risks, however, baseline rates for various age groups must be given serious consideration. Importance of other predisposing conditions mentioned above in determining relative and absolute risks has not as yet been quantified; quite likely the same synergistic action exists, but perhaps to a lesser extent.

RISK OF DOSE — In an analysis of data derived from several national adverse-reaction reporting systems, British investigators concluded that risk of thromboembolism, including coronary thrombosis, is directly related to dose of estrogen in OC's. Preparations containing 100 mcg or more of estrogen were associated with higher risk of thromboembolism than those containing 50-80 mcg. Their analysis did suggest, however, that quantity of estrogen may not be the sole factor involved. This finding has been confirmed in the U.S.

ESTIMATE OF EXCESS MORTALITY FROM CIRCULATORY DISEASES — A large prospective study carried out in the UK estimated the mortality rate per 100,000 women per year from diseases of the circulatory system for users and nonusers of OC's according to age, smoking habits, and duration of use. Overall excess death rate annually from circulatory diseases for OC users was estimated to be 20 per 100,000 (ages 15-34 — 5/100,000; ages 35-44 — 33/100,000; ages 45-49 — 140/100,000), risk being concentrated in older women, in those with long duration of use and in cigarette smokers. It was not possible, however, to examine interrelationships of age, smoking, and duration of use, nor to compare effects of continuous vs. intermittent use. Although the study showed a 10-fold increase in death due to circulatory diseases in users for 5 or more years, all these deaths occurred in women 35 or older. Until larger numbers of women under 35 with continuous use for 5 or more years are available, it is not possible to assess magnitude of relative risk for this younger group. Available data from a variety of sources have been analyzed to estimate risk of death associated with various methods of contraception. Estimates of risk of death for each method include combined risk of contraceptive method (e.g., thromboembolic and thrombotic disease in the case of OC's) plus risk attributable to pregnancy or abortion in event of method failure. This latter risk varies with effectiveness of method. The study concluded that mortality associated with all methods of birth control is low and below that associated with childbirth, with the exception of OC's in women over 40 who smoke. Lowest mortality is associated with condom or diaphragm backed up by early abortion. Risk of thromboembolic and thrombotic disease associated with OC's increases with age after about 30 and, for MI, is further increased by hypertension, hypercholesterolemia, obesity, diabetes, or history of pre-eclamptic toxemia, and especially cigarette smoking. Physician and patient should be alert to earliest manifestations of thromboembolic and thrombotic disorders (e.g., thrombophlebitis, pulmonary embolism, cerebrovascular insufficiency, coronary occlusion, retinal thrombosis, and mesenteric thrombosis). Should any of these occur or be suspected, the drug should be discontinued immediately. A 4- to 6-fold increased risk of postsurgery thromboembolic complications has been reported in OC users. If feasible, OC's should be discontinued at least 4 weeks before surgery of a type associated with increased risk of thromboembolism or prolonged immobilization.

PERSISTENCE OF RISK OF VASCULAR DISORDERS — Findings from one study in Britain involving cerebrovascular disease and another in the U.S. concerning MI suggest an increased risk of these conditions in users of OC's persists after discontinuation of the OC's. In the British study, risk of cerebrovascular disease remained elevated in former OC users for at least 6 years after discontinuation. In the U.S. study, increased risk of MI persisted for at least 9 years in women 40 to 49 years old who had used OC's for 5 or more years. Findings in both studies require confirmation since they are inconsistent with other published information.

2. *Ocular Lesions* — There have been reports of neuro-ocular lesions such as optic neuritis or retinal thrombosis associated with use of OC's. Discontinue OC's if there is unexplained, sudden or gradual, partial or complete loss of vision; onset of proptosis or diplopia; papilledema; or retinal-vascular lesions, and institute appropriate diagnostic and therapeutic measures.

3. *Carcinoma* — Long-term continuous administration of either natural or synthetic estrogen in certain animal species increases frequency of carcinoma of the breast, cervix, vagina, and liver. Certain synthetic progestogens, none currently contained in OC's, have been noted to increase incidence of mammary nodules, benign and malignant, in dogs. In humans, 3 case-control studies have reported an increased risk of endometrial carcinoma associated with prolonged use of exogenous estrogen in postmenopausal women. One publication reported on the first 21 cases submitted by physicians to a registry of cases of adenocarcinoma of the endometrium in women under 40 on OC's. Of cases found in women without predisposing risk factors (e.g., irregular bleeding at the time OC's were first given, polycystic ovaries), nearly all occurred in women who had used a sequential OC. These are no longer marketed. No evidence has been reported suggesting increased risk of endometrial cancer in users of conventional combination or progestogen-only OC's. Several studies have found no increase in breast cancer in women taking OC's or estrogens. One study, however, while also noting no overall increased risk of breast cancer in women on OC's, found an excess risk in subgroups of OC users with documented benign breast disease. Reduced occurrence of benign breast tumors in users of OC's has been well documented. In summary, there is at present no confirmed evidence from human studies of increased risk of cancer associated with OC's. Close clinical surveillance of all women on OC's is, nevertheless, essential. In all cases of undiagnosed persistent or recurrent abnormal vaginal bleeding, appropriate diagnostic measures should be taken to rule out malignancy. Women with a strong family history of breast cancer or with breast nodules, fibrocystic disease, or abnormal mammograms should be monitored with particular care if they elect to use OC's.

4. *Hepatic Tumors* — Benign hepatic adenomas have been found to be associated with use of OC's. One study showed that OC's with high hormonal potency were associated with higher risk than lower potency OC's. Although benign, hepatic adenomas may rupture and may cause death through intra-abdominal hemorrhage. This has been reported in short-term as well as long-term users. Two studies relate risk with duration of use of OC's, the risk being much greater after 4 or more years' use. While hepatic adenoma is rare, it should be considered in women presenting abdominal pain and tenderness, abdominal mass or shock. A few cases of hepatocellular carcinoma have been reported in women on OC's. Relationship of these drugs to this type of malignancy is not known.

5. *Use in or Immediately Preceding Pregnancy, Birth Defects in Offspring, and Malignancy in Female Offspring* — Use of female sex hormones — both estrogenic and progestational agents — during early pregnancy may seriously damage the offspring. It has been shown that females exposed in utero to diethylstilbestrol, a nonsteroidal estrogen, have increased risk of developing in later life a form of vaginal or cervical cancer ordinarily extremely rare. This risk has been estimated to be of the order of 1 in 1,000 exposures or less. Although there is no evidence now that OC's further enhance risk of developing this type of malignancy, such patients should be monitored with particular care if they elect to use OC's. Furthermore, 30 to 90% of such exposed women have been found to have epithelial changes c
vagina and cervix. Although these changes are histologically benign, it is not known whether this condition i
precursor of vaginal malignancy. Male children so exposed may develop abnormalities of the urogenital tract
similar data are not available with use of other estrogens, it cannot be presumed they would not induce simi
changes. An increased risk of congenital anomalies, including heart defects and limb defects, has been rep
use of sex hormones, including OC's, in pregnancy. One case-control study estimated a 4.7-fold increase in
limb-reduction defects in infants exposed in utero to sex hormones (OC's, hormonal withdrawal tests for pre
attempted treatment for threatened abortion). Some exposures involved only a few days. Data suggest that
limb-reduction defects in exposed fetuses is somewhat less than 1 in 1,000 live births. In the past, female
hormones have been used during pregnancy in an attempt to treat threatened or habitual abortion. There is
considerable evidence that estrogens are ineffective for these indications, and there is no evidence from we
controlled studies that progestogens are effective. There is some evidence that triploidy and possibly other
polyploidy are increased among abortuses from women who become pregnant soon after ceasing OC's. Em
these anomalies are virtually always aborted spontaneously. Whether there is an overall increase in spontan
abortion of pregnancies conceived soon after stopping OC's is unknown. It is recommended that, for any pa
has missed 2 consecutive periods, pregnancy should be ruled out before continuing OC's. If the patient has
adhered to the prescribed schedule, the possibility of pregnancy should be considered at time of first misse
and further use of OC's should be withheld until pregnancy has been ruled out. If pregnancy is confirmed, th
should be apprised of the potential risks to the fetus, and advisability of continuation of the pregnancy shou
discussed. It is also recommended that women who discontinue OC's with intent of becoming pregnant use
alternate form of contraception for a period of time before attempting to conceive. Many clinicians recomme
months, although no precise information is available on which to base this. The administration of progesto
combinations to induce withdrawal bleeding should not be used as a test of pregnancy.

6. *Gallbladder Disease* — Studies report increased risk of surgically confirmed gallbladder disease in users
estrogens. In one study, increased risk appeared after 2 years' use and doubled after 4 or 5 years' use. In o
other studies, increased risk was apparent between 6 and 12 months' use.

7. *Carbohydrate and Lipid Metabolic Effects* — Decrease in glucose tolerance has been observed in a signifi
percentage of patients on OC's. For this reason, prediabetic and diabetic patients should be carefully obser
OC's. Increases in triglycerides and total phospholipids have been observed in patients on OC's. Three stud
performed with Triphasil and no significant alterations in lipid metabolism were noted except for a slight inc
triglyceride levels in 1 study. Clinical significance of these findings remains to be defined.

8. *Elevated Blood Pressure* — Increase in blood pressure has been reported in patients on OC's. In some wo
hypertension may occur within a few months of beginning OC's. In the 1st year of use, prevalence of women
hypertension is low in users and may be no higher than that of a comparable group of nonusers. Prevalence
increases, however, with longer exposure, and in the 5th year of use is 2½ to 3 times the reported prevalen
1st year. Age is also strongly correlated with development of hypertension in OC users. Women who previou
had hypertension during pregnancy may be more likely to develop elevation of blood pressure on OC's. Hype
that develops as a result of taking OC's usually returns to normal after discontinuing the drug.

9. *Headache* — Onset or exacerbation of migraine or development of headache of a new pattern which is rec
persistent, or severe, requires discontinuation of OC's and evaluation of the cause.

10. *Bleeding Irregularities* — Breakthrough bleeding, spotting, and amenorrhea are frequent reasons for patie
discontinuing OC's. In breakthrough bleeding, as in all cases of irregular vaginal bleeding, nonfunctional cau
be borne in mind. In undiagnosed persistent or recurrent abnormal bleeding from the vagina, adequate diagn
measures are indicated to rule out pregnancy or malignancy. If pathology has been excluded, time or change
OC may solve the problem. Changing to an OC with a higher estrogen content, while potentially useful in mi
menstrual irregularity, should be done only if necessary, since this may increase risk of thromboembolic dise
Women with past history of oligomenorrhea or secondary amenorrhea or young women without regular cycle
a tendency to remain anovulatory or to become amenorrheic after discontinuing OC's. Women with these pre
problems should be advised of this possibility and encouraged to use other methods. Post-use anovulation,
prolonged, may also occur in women without previous irregularities.

11. *Ectopic Pregnancy* — Ectopic as well as intrauterine pregnancy may occur in contraceptive failures.

12. *Breast-feeding* — OC's given in the postpartum period may interfere with lactation and decrease quantity
of breast milk. Furthermore, a small fraction of the hormones in OC's has been identified in the milk of moth
OC's; effects, if any, on the breast-fed child have not been determined. If feasible, defer OC's until infant has b

Precautions — GENERAL — 1. A complete medical and family history should be taken prior to initiation of
Pretreatment and periodic physical examinations should include special reference to blood pressure, breast
and pelvic organs, including Pap smear and relevant laboratory tests. As a general rule OC's should not be p
for longer than 1 year without another physical examination and Pap smear. 2. Under influence of estrogen-p
preparations, preexisting uterine leiomyomata may increase in size. 3. Patients with history of psychic depre
should be carefully observed and the drug discontinued if depression recurs to a serious degree. Patients be
significantly depressed while on OC's should stop OC's and use an alternate method to try to determine wh
symptom is drug-related. 4. OC's may cause some degree of fluid retention. They should be prescribed with
and only with careful monitoring, in patients with conditions which might be aggravated by fluid retention, su
convulsive disorders, migraine syndrome, asthma, or cardiac or renal insufficiency. 5. Patients with a past hi
jaundice during pregnancy have an increased risk of recurrence while on OC's. If jaundice develops, OC's s
discontinued. 6. Steroid hormones may be poorly metabolized in patients with impaired liver function and sh
administered with caution. 7. OC users may have disturbances in normal tryptophan metabolism which may
relative pyridoxine deficiency. Clinical significance is undetermined. 8. Serum folate levels may be depresse
OC's. Since the pregnant woman is predisposed to development of folate deficiency and incidence of folate
increases with increasing gestation, it is possible that if a woman becomes pregnant shortly after stopping
may have a greater chance of developing folate deficiency and complications attributed to this deficiency. 9.
pathologist should be advised of OC therapy when relevant specimens are submitted. 10. Certain endocrine
liver-function tests and blood components may be affected by estrogen-containing OC's. a. Increased sulfobro
retention. b. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; increased nore
induced platelet aggregability. c. Increased thyroid-binding globulin (TBG) leading to increased circulating to
hormone, as measured by protein-bound iodine (PBI), T4 by column, or T4 by radioimmunoassay. Free T3 re
is decreased, reflecting the elevated TBG; free T4 concentration is unaltered. d. Decreased pregnanediol ex
e. Reduced response to metyrapone test.

Information for the Patient — See Patient Package Labeling.

Drug Interactions — Reduced efficacy and increased incidence of breakthrough bleeding have been assoc
concomitant use of rifampin. A similar association has been suggested with barbiturates, phenylbutazone, p
sodium, ampicillin and tetracycline.

Carcinogenesis — See Warnings section for information on carcinogenesis.

Pregnancy — Category X. See Contraindications, Warnings.

Nursing Mothers — See Warnings.

Adverse Reactions — An increased risk of these serious adverse reactions has been associated with use
(see Warnings): thrombophlebitis, pulmonary embolism, coronary thrombosis, cerebral thrombosis, cerebral
hypertension, gallbladder disease, benign hepatomas, congenital anomalies. There is evidence of an associ
between the following conditions and use of OC's although additional confirmatory studies are needed: mes
thrombosis, neuro-ocular lesions, e.g., retinal thrombosis and optic neuritis.

The following adverse reactions have been reported in patients on OC's and are believed to be drug-related.
and/or vomiting, usually the most common adverse reactions, occur in approximately 10 percent or less of
during the first cycle. Other reactions, as a general rule, are seen much less frequently or only occasionally.
Gastrointestinal symptoms (such as abdominal cramps and bloating); breakthrough bleeding, spotting, chan
menstrual flow: dysmenorrhea, amenorrhea during and after treatment, temporary infertility after discontinua
treatment; edema; chloasma or melasma which may persist; breast changes: tenderness, enlargement, and
change in weight (increase or decrease); change in cervical erosion and cervical secretion, possible diminut
lactation when given immediately postpartum; cholestatic jaundice; migraine; increase in size of uterine leio
rash (allergic); mental depression; reduced tolerance to carbohydrates; vaginal candidiasis; change in corne
(steepening); intolerance to contact lenses. The following adverse reactions have been reported in users of
the association has been neither confirmed nor refuted: premenstrual-like syndrome, cataracts, changes in
chorea, changes in appetite, cystitis-like syndrome, headache, nervousness, dizziness, hirsutism, loss of sc
erythema multiforme, erythema nodosum, hemorrhagic eruption, vaginitis, porphyria, hemolytic uremic syndr

Acute Overdose — Serious ill effects have not been reported following acute ingestion of large doses of O
young children. Overdosage may cause nausea, and withdrawal bleeding may occur in females.

Dosage and Administration — For maximum contraceptive effectiveness, Triphasil must be taken exactly
directed and at intervals not over 24 hours. (If Triphasil is first taken later than first day of first menstrual cy
medication or postpartum, contraceptive reliance should not be placed on it until after the first 7 consecutiv
of use. Possibility of ovulation and conception prior to initiation of medication should be considered.)
Any time patient misses 1 or 2 brown, white or light-yellow tablets, she should also use another contracept
until she has taken a tablet daily for 7 consecutive days. For full details on dosage and administration see p
information in package insert.

Clinical Opinion

Screening recommendations for gestational diabetes mellitus 493
Larry Cousins, MD, Laxmi Baxi, MD, Ronald Chez, MD, Donald Coustan, MD, Steven Gabbe, MD, Joseph Harris, MD, Mark Landon, MD, David Sacks, MD, and Shailini Singh, MD
San Diego, Los Angeles, and Bellflower, California, New York, New York, Tampa, Florida, Providence, Rhode Island, Columbus, Ohio, and Washington, D.C.

The "best" gestational diabetes mellitus screening approach is the universal use of a plasma glucose level 1 hour after a 50 gm oral glucose challenge; this test, performed at least once in pregnancy, uses a threshold no higher than 140 mg/dl.

Embryonic ultrasonographic measurements: Crown-rump length revisited 497
Steven R. Goldstein, MD
New York, New York

When reviewing the anatomy of very early embryos (length <18 mm), what we see and attempt to measure ultrasonographically is not actually a "crown-rump" length.

Clinical Articles

Ovarian cancer screening: Potential effect on mortality 502
Carolyn Westhoff, MD, MSc, and Mary Colleen Randall, MSc
New York, New York

Ovarian cancer screening will lead to only limited improvements in mortality, even if highly sensitive and specific screening tests are found.

Prenatal behavioral risk screening by computer in a health maintenance organization–based prenatal care clinic

Sandra C. Lapham, MD, MPH, Michael K. Kring, BSCS, and Betty Skipper, PhD
Albuquerque, New Mexico

A confidential patient-interactive computerized behavioral risk assessment was well received by prenatal patients and was found useful for patient education.

Short-term variation in abnormal antenatal fetal heart rate records

P. Street, MRCS, G.S. Dawes, DM, M. Moulden, and C.W.G. Redman, MB
Oxford, England

A computerized system is presented for antenatal care in which measurement of short-term variation in the fetal heart rate predicts metabolic acidemia or intrauterine death reliably.

Maturation of the uterine cervix by repeated intracervical instillation of prostaglandin E_2

Jacques M. Milliez, MD, Denis Jannet, MD, Claudine Touboul, MD, Mahfoudh El Medjadji, MD, and Bernard J. Paniel, MD
Créteil, France

Repeated intracervical instillations of 0.25 mg of prostaglandin E_2 were performed in patients with a high-risk pregnancy with no detrimental effect to the fetus.

Hypoplastic left heart syndrome: Prenatal diagnosis, clinical profile, and management

Danielle M. Blake, MD, Joshua A. Copel, MD, and Charles S. Kleinman, MD
New Haven, Connecticut

The prenatal diagnosis of hypoplastic left heart syndrome, while implying a poor prognosis for neonatal survival, provides the information needed by parents for informed decision-making.

Count on

CEFOTAN® IM/IV
(cefotetan disodium)

In intra-abdominal and gynecologic infection due to indicated organisms

For Intravenous or Intramuscular Use
(FOR FULL PRESCRIBING INFORMATION, SEE PACKAGE INSERT.)

INDICATIONS AND USAGE

Treatment: CEFOTAN is indicated for the therapeutic treatment of the following infections when caused by susceptible strains of the designated organisms:

Urinary Tract Infections caused by *E coli*, *Klebsiella* species (including *K pneumoniae*), *Proteus mirabilis*, and *Proteus* sp (which may include the organisms now called *Proteus vulgaris*, *Providencia rettgeri*, and *Morganella morganii*).

Lower Respiratory Tract Infections caused by *Streptococcus pneumoniae* (formerly *D pneumoniae*), *Staphylococcus aureus* (penicillinase- and nonpenicillinase-producing strains), *Haemophilus influenzae* (including ampicillin-resistant strains), *Klebsiella* species (including *K pneumoniae*), *E coli*, *Proteus mirabilis*, and *Serratia marcescens*.*

Skin and Skin Structure Infections caused by *Staphylococcus aureus* (penicillinase- and nonpenicillinase-producing strains), *Staphylococcus epidermidis*, *Streptococcus pyogenes*, *Streptococcus* species (excluding enterococci), *E coli*, *Klebsiella pneumoniae*, and *Peptococcus** and *Peptostreptococcus* sp.*

Gynecologic Infections caused by *Staphylococcus aureus* (including penicillinase- and nonpenicillinase-producing strains), *Staphylococcus epidermidis*, *Streptococcus* species (excluding enterococci), group B streptococci, *E coli*, *Proteus mirabilis*, *Neisseria gonorrhoeae*, *Bacteroides* species (excluding *B distasonis*, *B ovatus*, *and B thetaiotaomicron*), *Fusobacterium* species,* and gram-positive anaerobic cocci (including *Peptococcus* and *Peptostreptococcus* species).

Intra-abdominal Infections caused by *E coli*, *Klebsiella* species (including *K pneumoniae*), *Streptococcus* species (excluding enterococci), *Bacteroides* species (excluding *B distasonis*, *B ovatus*, and *B thetaiotaomicron*), and *Clostridium* species.*

Bone and Joint Infections caused by *Staphylococcus aureus*.*

*Efficacy for this organism in this organ system was studied in fewer than ten infections.

Specimens for bacteriological examination should be obtained in order to isolate and identify causative organisms and to determine their susceptibilities to cefotetan. Therapy may be instituted before results of susceptibility studies are known; however, once these results become available, the antibiotic treatment should be adjusted accordingly.

In cases of confirmed or suspected gram-positive or gram-negative sepsis or in patients with other serious infections in which the causative organism has not been identified, it is possible to use CEFOTAN concomitantly with an aminoglycoside. Cefotetan combinations with aminoglycosides have been shown to be synergistic in vitro against many Enterobacteriaceae and also some other gram-negative bacteria. The dosage recommended in the labeling of both antibiotics may be given and depends on the severity of the infection and the patient's condition.

Note: If CEFOTAN and an aminoglycoside are used concomitantly, renal function should be carefully monitored, especially if higher dosages of the aminoglycoside are to be administered or if therapy is prolonged, because of the potential nephrotoxicity and ototoxicity of aminoglycosidic antibiotics. Although, to date, nephrotoxicity has not been noted when CEFOTAN was given alone, it is possible that nephrotoxicity may be potentiated if CEFOTAN is used concomitantly with an aminoglycoside.

Prophylaxis: The preoperative administration of CEFOTAN may reduce the incidence of certain postoperative infections in patients undergoing surgical procedures that are classified as clean contaminated or potentially contaminated (eg, cesarean section, abdominal or vaginal hysterectomy, transurethral surgery, biliary tract surgery, and gastrointestinal surgery).

The prophylactic dose of CEFOTAN should be administered 30 to 60 minutes prior to surgery. In patients undergoing cesarean section, CEFOTAN should be administered intravenously after the clamping of the umbilical cord.

If there are signs and symptoms of infection, specimens for culture should be obtained for identification of the causative organism so that appropriate therapeutic measures may be initiated.

CONTRAINDICATIONS

CEFOTAN is contraindicated in patients with known allergy to the cephalosporin group of antibiotics.

WARNINGS

Before therapy with CEFOTAN is instituted, careful inquiry should be made to determine whether the patient has had previous hypersensitivity reactions to cefotetan disodium, cephalosporins, penicillins, or other drugs. This product should be given cautiously to penicillin-sensitive patients. Antibiotics should be administered with caution to any patient who has demonstrated some form of allergy, particularly to drugs. If an allergic reaction to CEFOTAN occurs, discontinue the drug. Serious acute hypersensitivity reactions may require epinephrine and other emergency measures.

Pseudomembranous colitis has been reported with the use of cephalosporins (and other broad-spectrum antibiotics); therefore, it is important to consider its diagnosis in patients who develop diarrhea in association with antibiotic use.

Treatment with broad-spectrum antibiotics may alter normal flora of the colon and may permit overgrowth of clostridia. Studies indicate a toxin produced by *Clostridium difficile* is one primary cause of antibiotic-associated colitis.

Mild cases of colitis may respond to drug discontinuance alone. Moderate to severe cases should be managed with fluid, electrolyte, and protein supplementation as indicated. When the colitis is not relieved by drug discontinuance, or when it is severe, oral vancomycin is the treatment of choice for antibiotic-associated pseudomembranous colitis produced by *C difficile*. Other causes should also be considered.

In common with many other broad-spectrum antibiotics, CEFOTAN may be associated with a fall in prothrombin activity and, possibly, subsequent bleeding. Those at increased risk include patients with renal or hepatobiliary impairment or poor nutritional state, the elderly, and patients with cancer. Prothrombin time should be monitored and exogenous vitamin K administered as indicated.

PRECAUTIONS

General: As with other broad-spectrum antibiotics, prolonged use of CEFOTAN may result in overgrowth of nonsusceptible organisms. Careful observation of the patient is essential. If superinfection does occur during therapy, appropriate measures should be taken.

CEFOTAN should be used with caution in individuals with a history of gastrointestinal disease, particularly colitis.

Information for Patients: As with some other cephalosporins, a disulfiram-like reaction characterized by flushing, sweating, headache, and tachycardia may occur when alcohol (beer, wine, etc.) is ingested within 72 hours after CEFOTAN administration. Patients should be cautioned about the ingestion of alcoholic beverages following the administration of CEFOTAN.

Drug Interactions: Although to date nephrotoxicity has not been noted when CEFOTAN was given alone, it is possible that nephrotoxicity may be potentiated if CEFOTAN is used concomitantly with an aminoglycoside.

Drug/Laboratory Test Interactions: A false positive reaction for glucose in urine may occur with Benedict's or Fehling's solution.

As with other cephalosporins, high concentrations of cefotetan may interfere with measurement of serum and urine creatinine levels by Jaffe reaction and produce false increases in the levels of creatinine reported.

Carcinogenesis, Mutagenesis, Impairment of Fertility: Although long-term studies in animals have not been performed to evaluate carcinogenic potential, no mutagenic potential of cefotetan was found in standard laboratory tests.

Cefotetan has adverse effects on the testes of prepubertal rats. Subcutaneous administration of 500 mg/kg/day (approximately 8-16 times the usual adult human dose) on days 6-35 of life (thought to be developmentally analogous to late childhood and prepuberty in humans) resulted in reduced testicular weight and seminiferous tubule degeneration in 10 of 10 animals. Affected cells included spermatogonia and spermatocytes; Sertoli and Leydig cells were unaffected. Incidence and severity of lesions were dose-dependent; at 120 mg/kg/day (approximately 2-4 times the usual human dose) only 1 of 10 treated animals was affected, and the degree of degeneration was mild.

Similar lesions have been observed in experiments of comparable design with other methylthiotetrazole-containing antibiotics and impaired fertility has been reported, particularly at high dose levels. No testicular effects were observed in 7-week-old rats treated with up to 1000 mg/kg/day SC for 5 weeks, or in infant dogs (3 weeks old) that received up to 300 mg/kg/day IV for 5 weeks. The relevance of these findings to humans is unknown.

Usage in Pregnancy: Pregnancy Category B: Reproduction studies have been performed in rats and monkeys at doses up to 20 times the human dose and have revealed no evidence of impaired fertility or harm to the fetus due to cefotetan. There are, however, no adequate and well-controlled studies in pregnant women. Because animal reproductive studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.

Usage in Nursing Mothers: Cefotetan is excreted in human milk in very low concentrations. Caution should be exercised when cefotetan is administered to a nursing woman.

Pediatric Use: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS

In clinical studies, the following adverse effects were considered related to CEFOTAN therapy.

Gastrointestinal symptoms occurred in 1.5% of patients; the most frequent were diarrhea (1 in 80) and nausea (1 in 700).

Hematologic laboratory abnormalities occurred in 1.4% of patients and included eosinophilia (1 in 200), positive direct Coombs' test (1 in 250), and thrombocytosis (1 in 300).

Hepatic enzyme elevations occurred in 1.2% of patients and included a rise in SGPT (1 in 150), SGOT (1 in 300), alkaline phosphatase (1 in 700), and LDH (1 in 700).

Hypersensitivity reactions were reported in 1.2% of patients and included rash (1 in 150) and itching (1 in 700).

Local effects were reported in less than 1.0% of patients and included phlebitis at the site of injection (1 in 300), and discomfort (1 in 500).

During postmarketing experience with CEFOTAN, agranulocytosis, anaphylactic reactions, fever, hemolytic anemia, leukopenia, prolonged prothrombin time with or without bleeding, pseudomembranous colitis, and transient thrombocytopenia have been reported.

DOSAGE AND ADMINISTRATION

Treatment: The usual adult dosage is 1 or 2 grams of CEFOTAN administered intravenously or intramuscularly every 12 hours for 5 to 10 days. Proper dosage and route of administration should be determined by the condition of the patient, severity of the infection, and susceptibility of the causative organism.

GENERAL GUIDELINES FOR DOSAGE OF CEFOTAN

Type of Infection	Daily Dose	Frequency and Route
Urinary Tract	1-4 grams	500 mg every 12 hours IV or IM 1 or 2 g every 24 hours IV or IM 1 or 2 g every 12 hours IV or IM
Other Sites	2-4 grams	1 or 2 g every 12 hours IV or IM
Severe	4 grams	2 g every 12 hours IV
Life-Threatening	6* grams	3 g every 12 hours IV

*Maximum daily dosage should not exceed 6 grams.

Prophylaxis: To prevent postoperative infection in clean contaminated or potentially contaminated surgery in adults, the recommended dosage is 1 or 2 g of CEFOTAN administered once, intravenously, 30 to 60 minutes prior to surgery. In patients undergoing cesarean section, the dose should be administered as soon as the umbilical cord is clamped.

Impaired Renal Function: When renal function is impaired, a reduced dosage schedule must be employed. The following dosage guidelines may be used.

DOSAGE GUIDELINES FOR PATIENTS WITH IMPAIRED RENAL FUNCTION

Creatinine Clearance mL/min	Dose	Frequency
>30	Usual Recommended Dosage*	Every 12 hours
10-30	Usual Recommended Dosage*	Every 24 hours
<10	Usual Recommended Dosage*	Every 48 hours

*Dose determined by the type and severity of infection, and susceptibility of the causative organism.

Alternatively, the dosing interval may remain constant at 12 hour intervals, but the dose reduced to one-half the usual recommended dose for patients with a creatinine clearance of 10-30 mL/min, and one-quarter the usual recommended dose for patients with a creatinine clearance of less than 10 mL/min.

When only serum creatinine levels are available, creatinine clearance may be calculated from the following formula. The serum creatinine level should represent a steady state of renal function.

$$\text{Males:} \quad \frac{\text{Weight (kg)} \times (140 - \text{age})}{72 \times \text{serum creatinine (mg/100 mL)}}$$

$$\text{Females:} \quad 0.9 \times \text{value for males}$$

Cefotetan is dialyzable and it is recommended that for patients undergoing intermittent hemodialysis, one-quarter of the usual recommended dose be given every 24 hours on days between dialysis and one-half the usual recommended dose on the day of dialysis.

Adrenal and ovarian steroid hormone responses to gonadotropin-releasing hormone agonist treatment in polycystic ovary syndrome 535
Frank Gonzalez, MD, Denise A. Hatala, BS, and Leon Speroff, MD
Cleveland, Ohio

In polycystic ovary syndrome, ovarian steroids may promote excess adrenal androgen secretion and induce 3β-hydroxysteroid dehydrogenase deficiency as a mechanism of adrenal involvement but do not influence the adrenal androgen response to pharmacologic corticotropin administration.

Management of fetal hemolytic disease by cordocentesis. I. Prediction of fetal anemia 546
Carl P. Weiner, MD, Roger A. Williamson, MD, Katharine D. Wenstrom, MD, Susan L. Sipes, MD, Stanley S. Grant, RN, and John A. Widness, MD
Iowa City, Iowa

Evaluation of fetal blood permits the identification of fetuses at high risk for severe hemolytic disease.

Steroid therapy for hydrops associated with antibody-mediated congenital heart block 553
William J. Watson, MD, and Vern L. Katz, MD
Chapel Hill, North Carolina

Hydrops in a fetus with antibody-mediated heart block was improved by maternal steroid therapy.

Prognostic factors and complication rates for cervical cerclage: A review of 482 cases 555
Marjorie C. Treadwell, MD, Richard A. Bronsteen, MD, and Sidney F. Bottoms, MD
Detroit, Michigan

When cerclage was performed, dilatation had a greater impact on pregnancy outcome than did gestational age, and Shirodkar cerclage may be preferred in patients undergoing repeat procedures.

Incidental appendectomy during videolaseroscopy 559
Camran Nezhat, MD, and Farr Nezhat, MD
Atlanta, Georgia

One hundred consecutive, complication-free, incidental appendectomies with the carbon dioxide laser in patients of reproductive age undergoing operative laparoscopy (videolaseroscopy) are described.

Use of hydroxyurea in chronic myeloid leukemia during pregnancy: A case report 565
M. Patel, MB, ChB, MMed(Wits), I.A.F. Dukes, MB, ChB, and J.C. Hull, MB, ChB
Johannesburg, South Africa

Use of hydroxyurea in chronic myeloid leukemia during pregnancy resulted in a successful outcome for both mother and fetus.

THE NATURAL CHOICE

GORE-TEX®
SOFT TISSUE PATCH

In reconstructive surgery, a patient's own tissue is not always adequate. However, today surgeons do have alternatives. When a biomaterial is indicated, the GORE-TEX Soft Tissue Patch is the natural choice.

This remarkable sheet of GORE-TEX (expanded polytetrafluoroethylene) is engineered to provide improved performance in a wide range of applications. Since its introduction in 1982, the GORE-TEX Soft Tissue Patch has been used in more than 50,000 clinical cases worldwide.

The GORE-TEX Soft Tissue Patch combines high, balanced strength with softness and conformability. It is easy to shape and contour without fraying. Its microporous structure allows natural tissue ingrowth leading to potential treatability in the presence of infection. Next to delicate internal organs, the GORE-TEX Soft Tissue Patch has shown a significant reduction in adhesion formation and tissue erosion.

The exceptional versatility of the GORE-TEX Soft Tissue Patch makes it the natural choice in a wide range of applications.

- Abdominal Wall Reconstruction
- Hernia Repair
- Thoracic Wall Reconstruction
- Diaphragm Reconstruction
- Rectal and Vaginal Suspension
- Urethral Suspension
- Gastric Banding
- Facial Augmentation and Sling Procedures
- Related Pediatric Reconstructions

☐ Please send further information on the GORE-TEX Soft Tissue Patch.
☐ Please arrange for a free clinical sample.
☐ Please have your sales representative call for an appointment.

Chapel Hill, North Carolina

Hexamethylmelamine is a well-tolerated drug with activity against ovarian cancer previously treated with cisplatin.

Fetal breathing movements before oxytocin induction in prolonged pregnancies 577

Peter Schreyer, MD, Naomi Bar-Natan, MD, Dan J. Sherman, MD, Shlomo Arieli, MD, and Eliahu Caspi, MD

Zerifin, Israel

Fetal breathing movements recorded before induction of labor in postdate pregnancies are a reliable indicator of the time and quantity of oxytocin required throughout labor.

Risks associated with an elevated maternal serum α-fetoprotein level 581

Barbara F. Crandall, MD, Linda Robinson, MS, and Peggy Grau, MD

Los Angeles, California

Risks for both fetal abnormality and adverse pregnancy outcome increase directly with maternal serum α-fetoprotein levels.

Study of 156 cases of polyhydramnios and congenital malformations in a series of 118,265 consecutive births 586

Claude G. Stoll, MD, Yves Alembik, MD, and Beatrice Dott, MD

Strasbourg, France

The diagnosis of congenital malformations was performed in only 41% of 156 cases of polyhydramnios associated with congenital anomalies.

Regulation of atrial natriuretic peptide release in pregnancy: Responses to posture 591

Sandra A. Lowe, MB, Graham J. Macdonald, MD, and Mark A. Brown, MD

Sydney, Australia

Atrial natriuretic peptide is stimulated in normal pregnancy by prolonged recumbency, inhibited by upright posture, and unchanged by supine posture.

Continuation...an excellent indicator of patient satisfaction.

The Ortho ALL-FLEX* Arcing Spring Diaphragm

☐ Easy to insert and position
☐ Easy to clean and maintain
☐ Easy to use with unscented, colorless, stainless GYNOL II* (2% nonoxynol-9) Contraceptive Jelly
☐ The combination for continuation—with 4 out of 5 patients continuing after 1 year†

Continuation...it's one reason why physicians continue to make ORTHO ALL-FLEX and GYNOL II the #1 prescribed diaphragm combination in America.‡

Single and multiple administration of a new triphasic oral contraceptive to women: Pharmacokinetics of ethinyl estradiol and free and total testosterone levels in serum 596

Wilhelm Kuhnz, PhD, Durda Sostarek, Christiane Gansau, Tom Louton, PhD, and Marianne Mahler, MD
Berlin, Germany

During long-term administration of a triphasic formulation containing gestodene and ethinyl estradiol, mean serum levels of ethinyl estradiol that were reached were higher than those observed after single-dose administration; total and free testosterone concentrations were equally suppressed during treatment.

Oral tocolysis with magnesium chloride: A randomized controlled prospective clinical trial 603

Jean M. Ricci, MD, Seemanthini Hariharan, MD, Andrew Helfgott, MD, Karel Reed, RN, and Mary Jo O'Sullivan, MD
Miami, Florida, and Los Angeles, California

A prospective clinical trial to determine the efficacy and safety of oral magnesium chloride as a tocolytic agent is presented.

The effects of betamethasone on maternal cellular resistance to infection 610

Dean S. Cunningham, MD, PhD, and Edward E. Evans, MD
Portsmouth, Virginia

The antenatal administration of betamethasone for fetal lung maturation does not result in impairment of maternal immune responsiveness.

Vasopressin and operative hysteroscopy in the management of delayed postabortion and postpartum bleeding 616

Duane E. Townsend, MD, Solon D. Barbis, MD, and Roger D. Mathews, MD
Sacramento, California

Dilute vasopressin coupled with operative hysteroscopy was effective in controlling postabortion and postpartum bleeding.

Computerized analysis of episodic changes in fetal heart rate variation in early labor 618

G.S. Dawes, DM, S.K. Rosevear, MD, L.C. Pello, MD, M. Moulden, and C.W.G. Redman, MD
Oxford, England

Computerized measurement shows that cyclic episodes of low fetal heart rate variation persist in labor at a size readily mistaken for evidence of fetal distress.

Ultrasonographic diagnosis of symptomatic deep venous thrombosis in pregnancy 625

Joseph F. Polak, MD, and Diane L. Wilkinson, MD
Boston, Massachusetts

A prospective ultrasonographic evaluation of pregnant patients shows the incidence and pattern of symptomatic deep vein thrombosis to be similar to those of historic controls who have undergone venography.

Treatment of fetal supraventricular tachycardia with flecainide acetate after digoxin failure 630

Alexander D. Kofinas, MD, Nicolas V. Simon, MD, Henry Sagel, DO, Ellen Lyttle, RN, Nancy Smith, RN, and Karen King, RDMS
York, Pennsylvania

A case of successful treatment of fetal supraventricular tachycardia with flecainide acetate after digoxin failure is reported.

Antimicrobial therapy in preterm premature rupture of membranes: Results of a prospective, double-blind, placebo-controlled trial of erythromycin 632

James A. McGregor, MD, CM, Janice I. French, CNM, MS, and Kyung Seo, MD, PhD
Denver, Colorado

Erythromycin treatment was associated with prolonged pregnancy among mother-newborn pairs with preterm premature rupture of membranes between 28 and 32 weeks' gestation.

Expression and amplification of the HER-2/*neu* (c-*erb*B-2) protooncogene in epithelial ovarian tumors and cell lines 640

F.L. Tyson, PhD, C.M. Boyer, PhD, R. Kaufman, MD, K. O'Briant, MS, G. Cram, BS, J.R. Crews, MD, J.T. Soper, MD, L. Daly, BHS, W.C. Fowler, Jr., MD, J.S. Haskill, PhD, and R.C. Bast, Jr., MD
Durham and Chapel Hill, North Carolina

The oncogenes c-*erb*B-2, c-*fms*, c-*myc*, n-*myc*, c-*fos*, and c-Ha-*ras* are expressed in a large fraction of ovarian cancers and deserve further evaluation as prognostic factors.

Simultaneous measurements of prostacyclin and thromboxane metabolites during the menstrual cycle 647

Steven C. Presser, MD, Frank Z. Stanczyk, PhD, and Rogerio A. Lobo, MD
Los Angeles, California

Measurement of the stable urinary metabolites prostacyclin and thromboxane during the menstrual cycle suggests a hormone-mediated modulation of vasoactive prostanoids.

Recurrent mild abruptio placentae occurring immediately after repeated electroconvulsive therapy in pregnancy 652

David M. Sherer, MD, Mary Lou D'Amico, RNC, BSN, David P. Warshal, MD, Robert A. Stern, MD, Harold F. Grunert, MD, and Jacques S. Abramowicz, MD
Rochester, New York

Recurrent abruptio placentae, noted immediately after electroconvulsive therapy during pregnancy, might be explained by transient acute hypertension occurring in conjunction with this treatment.

Funic reduction for the management of umbilical cord prolapse 654

Jeffrey M. Barrett, MD
Lakeland, Florida

Vaginal delivery was accomplished without fetal damage after funic reduction in five patients with umbilical cord prolapse.

Contents

Adverse psychologic consequences of positive cytologic cervical screening 658

Caryn Lerman, PhD, Suzanne M. Miller, PhD, Ruth Scarborough, MEd, Parviz Hanjani, MD, Susan Nolte, RN, and David Smith, MD

Philadelphia, Pennsylvania

Substantial psychologic distress and impairment were observed among minority women who received positive results after cervical screening.

Prospective evaluation of maternal serum human chorionic gonadotropin levels in 3428 pregnancies 663

Mark H. Bogart, PhD, O.W. Jones, MD, Robin A. Felder, PhD, Robert G. Best, PhD, Linda Bradley, PhD, William Butts, PhD, Barbara Crandall, MD, Wendy MacMahon, BS, Frank H. Wians, Jr., PhD, and Paulette V. Loeh, BS

La Jolla and Los Angeles, California, Charlottesville, Virginia, Columbia, South Carolina, Chandler, Arizona, Renton, Washington, Decatur, Georgia, and Lackland, Texas

Evaluation of human chorionic gonadotropin levels during the second trimester of pregnancies with normal outcomes indicates that race and weight adjustments are necessary in screening for fetal Down syndrome.

Fetal atrioventricular and outflow tract flow velocity waveforms during normal second half of pregnancy 668

Karin van der Mooren, MD, Leo G. Barendregt, and Juriy W. Wladimiroff, MD, PhD

Rotterdam, The Netherlands

Fetal cardiac flow studies suggest a rise in ventricular stroke volume and a reduction in ventricular afterload during the second half of pregnancy.

Effect of cigarette smoking on maternal airway function during pregnancy 675

Tarun K. Das, PhD, Jean-Marie Moutquin, MD, and Jean-Guy Parent, MD

Quebec City, Quebec, Canada

The bronchodilatory effect expected in pregnancy is not sufficient to overcome the deleterious effect of cigarette smoking on maternal airway function.

Effectiveness of antibiotic prophylaxis in preventing bacteriuria after multichannel urodynamic investigations: A blind, randomized study in 124 female patients 679

Kevin R. Baker, MD, Harold P. Drutz, MD, and Mary D. Barnes, RN, BA

Toronto, Ontario, Canada

A blind, randomized prospective study investigates the effectiveness of prophylactic antibiotics in preventing bacteriuria after multichannel urodynamic investigations in 124 women.

Genetic identification of pregnancies responsible for choriocarcinomas after multiple pregnancies by restriction fragment length polymorphism analysis 682

Hisao Osada, MD, Makoto Kawata, MD, PhD, Masao Yamada, PhD, Ko Okumura, MD, PhD, and Hiroyoshi Takamizawa, MD, PhD

Chiba and Tokyo, Japan

The pregnancies responsible for two choriocarcinomas preceded by multiple pregnancies were determined by restriction fragment length polymorphism of human leukocyte antigen–DQ genes.

Transvaginal fetal echocardiography in early pregnancy: Normative data 688

Lawrence A. Dolkart, MD, and Faith T. Reimers, RNC, BS, RDMS

Elmira, New York

Transvaginal ultrasonography can be used to visualize normal fetal cardiac anatomy in the late first and early second trimesters.

Effects of angiotensin II on atrial natriuretic peptide in pregnancy 692

Marion A.L. Didden, MD, Marcel P. Hoekstra, MD, Jos H.A. Vollebergh, MD, Andries Schellekens, PhD, and Pieter A. de Jong, PhD

Eindhoven, The Netherlands

A rise in the level of atrial natriuretic peptide during infusion of angiotensin II seems to be mediated not only by changes in blood pressure but also by angiotensinergic receptor activity in the atria.

Expression of cytokine receptors and markers of differentiation in human papillomavirus–infected cervical tissues 696

Ronald C. McGlennen, MD, Ronald S. Ostrow, PhD, Linda F. Carson, MD, Michael S. Stanley, MD, and Anthony J. Faras, PhD

Minneapolis, Minnesota

The expression of epidermal growth factor, transferrin receptors, and cytokeratin is correlated with various histologic grades of human papillomavirus–infected cervical tissues.

Hemostatic wrapping of ruptured liver in two postpartum patients 705

Andrew B. Rittenberry, Jr., MD, Colman L. Arnold, MD, and M. Mark Taslimi, MD

Chattanooga, Tennessee

Hemostatic wrapping effectively controlled bleeding of ruptured liver in two postpartum patients.

Relationship between fetal biophysical activities and umbilical cord blood gas values 707

Anthony M. Vintzileos, MD, Alfred D. Fleming, MD, William E. Scorza, MD, Edward J. Wolf, MD, James Balducci, MD, Winston A. Campbell, MD, and John F. Rodis, MD

Farmington, Connecticut

Fetuses with absence of fetal movements or fetal tone have significantly lower cord blood pH, Po_2, bicarbonate, and base excess values and higher Pco_2 levels as compared with fetuses with nonreactive nonstress test results or absence of breathing.

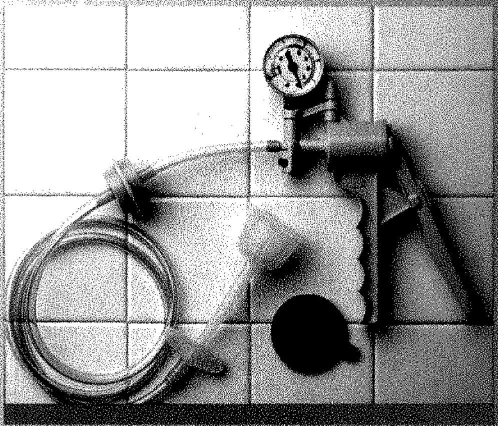
CALL FOR DETAILS

We've Been Giving Doctors A Hand For Over Twenty Years.

And they've given us a hand in designing and refining the best obstetrical vacuum delivery system available.

Over twenty years ago, the Mityvac vacuum delivery system was introduced to provide an alternative method of delivery assistance. In that time we've learned a great deal about our system from the professionals who use it, and have incorporated what we've learned into real product improvements. Today, Mityvac is regarded by many obstetric physicians as the safest, most dependable method of vacuum extraction.

The Mityvac Obstetrical Vacuum Delivery System offers benefits available with no other vacuum extraction system, like sensitive fingertip controls which allow the operator to adjust vacuum pressure to coincide with the natural efforts of the mother. In addition, the soft polyethylene extractor cup is flexible enough for ease of insertion, yet seals easily to the infant's scalp distributing tractive force across a large area. The Mityvac system offers greater control and insures minimal trauma to both infant and mother.



In vacuum extraction systems, Mityvac is the name that more obstetric physicians have come to know and depend on than any other. Mityvac. . .offering a hand for over twenty years.

Prenatal diagnosis of fetal cytomegalovirus infection 714

Lauren Lynch, MD, Fernand Daffos, MD, David Emanuel, MD, Yves Giovangrandi, MD, Richard Meisel, MD, Francois Forestier, PhD, Gieri Cathomas, MD, and Richard L. Berkowitz, MD
New York, New York, and Paris, France

Prenatal diagnosis of fetal cytomegalovirus infection is possible with a combination of amniocentesis and fetal blood sampling.

Increased inducibility of inflammatory mediators from peripheral blood mononuclear cells of women with salpingitis 719

Steven S. Witkin, PhD, Miklos Toth, MD, Jan Jeremias, AB, and William J. Ledger, MD
New York, New York

Peripheral blood mononuclear cells from women with salpingitis produce monokines under conditions in which the corresponding cells from other women remain unresponsive.

Maternal plasma level of endothelin is increased in preeclampsia 724

Alfredo Nova, MD, Baha M. Sibai, MD, John R. Barton, MD, Brian M. Mercer, MD, and Murray D. Mitchell, PhD
Memphis, Tennessee, and Salt Lake City, Utah

Plasma endothelin values are increased in women with preeclampsia, particularly in those with HELLP syndrome (hemolysis, elevated liver enzymes, and low platelet count).

In utero fetal muscle biopsy for the diagnosis of Duchenne muscular dystrophy 728

Mark I. Evans, MD, Anne Greb, MS, Louis M. Kunkel, PhD, Alan J. Sacks, MD, Mark P. Johnson, MD, Corinne Boehm, MS, Haig H. Kazazian, Jr., MD, and Eric P. Hoffman, PhD
Detroit, Michigan, Boston, Massachusetts, and Baltimore, Maryland

An in utero fetal muscle biopsy specimen was obtained from a male fetus at risk for Duchenne muscular dystrophy; it was analyzed for the dystrophin protein.

Concentration of digoxin-like immunoreactive substance in patients with preeclampsia and its relation to severity of pregnancy-induced hypertension 733

Krzysztof Kaminski, MD, PhD, and Tomasz Rechberger, MD, PhD
Lublin, Poland

A positive significant correlation between maternal serum concentration of digoxin-like immunoreactive substance and severity of preeclampsia was found.

A new proline aminopeptidase assay for diagnosis of bacterial vaginosis 737

Judith N. Schoonmaker, PhD, Brenda D. Lunt, MS, David W. Lawellin, PhD, Janice I. French, CNM, MS, Sharon L. Hillier, PhD, and James A. McGregor, MDCM
Denver, Colorado, and Seattle, Washington

An improved laboratory test for proline aminopeptidase is presented for use in the diagnosis of bacterial vaginosis.

Contents

Pemphigus gestationis (herpes gestationis): A case report 743

Igal Wolman, MD, Joseph Ophir, MD, David Pauzner, MD, Sarah Brenner, MD, and Menachem P. David, MD

Tel Aviv, Israel

Pemphigus gestationis is a rare disease with a high rate of morbidity and mortality to the fetus; a report of successful treatment of this disease is presented.

Current Development

Pelvic denervation for chronic pain associated with endometriosis: Fact or fancy? 745

Paolo Vercellini, MD, Luigi Fedele, MD, Stefano Bianchi, MD, and Giovanni Battista Candiani, MD

Milan, Italy

Analysis of literature data fails to confirm the effectiveness of presacral neurectomy and amputation of uterosacral ligaments in women with chronic pelvic pain associated with endometriosis.

BASIC SCIENCE SECTION

Inhibin subunits in human placenta: Localization and messenger ribonucleic acid levels during pregnancy 750

Felice Petraglia, MD, Gian Carlo Garuti, MD, Laura Calza', MD, Veronica Roberts, PhD, Luciana Giardino, MD, Andrea R. Genazzani, MD, Wylie Vale, PhD, and Helene Meunier, PhD

Modena and Cagliari, Italy, La Jolla, California, and Toronto, Ontario, Canada

Human cytotrophoblast and syncytiotrophoblast cells begin to produce inhibin and activin early in gestation, with the highest production rate at term.

Circadian rhythms of heart rate and mean arterial pressure in chronically instrumented pregnant rats 758

Paula J. Melone, DO, Paul J. Meis, MD, and David A. Blizard, PhD

Winston-Salem, North Carolina

Normotensive pregnant rats monitored continuously over the last half of gestation showed statistically significant circadian rhythms in heart rate and blood pressure; blood pressure decreased near term, but heart rate increased.

Bilateral destruction of the fetal paraventricular nuclei prolongs gestation in sheep 764

Thomas J. McDonald, PhD, and Peter W. Nathanielsz, MD, PhD

Ithaca, New York

Bilateral destruction of the fetal hypothalamic paraventricular nuclei prolongs gestation and prevents the increases in fetal plasma adrenocorticotropic hormone and cortisol that normally accompany parturition.

The effect of interleukin-1 on adhesion formation in the rat 771

Avner Hershlag, MD, Ivan G. Otterness, PhD, Marcia L. Bliven, BS, MT(ASCP), Michael P. Diamond, MD, and Mary Lake Polan, MD, PhD
New Haven and Groton, Connecticut

Interleukin-1 potentiates adhesions resulting from cecal abrasion but does not lead to adhesion formation in nontraumatized animals; this effect occurs only when interleukin-1 is administered in the acute stage of serosal trauma.

Acute fetal ductal occlusion in lambs 775

Gerald Tulzer, MD, Saemundur Gudmundsson, MD, PhD, Kathleen M. Rotondo, MD, Dennis C. Wood, RDMS, RCPT, Grace Y. Yoon, MPH, and James C. Huhta, MD
Philadelphia, Pennsylvania

Acute fetal ductal occlusion in lambs caused reversible tricuspid regurgitation, decreased right ventricular shortening fraction and output, and increased left ventricular output.

Calcium every day
Aerobics every wee
Bone loss every yea

She needs PREMARIN to help prevent further bone loss

Calcium[1] and exercise are not enough to prevent postmenopausal osteoporosis, since estrogen deficiency is the primary cause.[2] PREMARIN is the only brand of estrogen indicated to prevent further bone loss and in a recently published study has been shown to reduce the risk of hip fractures by as much as 66%.[3]

Early PREMARIN therapy offers the best protection

The most significant rate of bone loss occurs in early menopause. PREMARIN can help maintain bone mass, preventing the progression of osteoporosis and its consequences.

Protection continues as long as estrogen therapy continues

Clinical studies show that within three years of menopause when therapy is withdrawn, bone loss begins again.[4]

PREMARIN®

(conjugated estrogens tablets)

Proven benefits for menopause and beyond

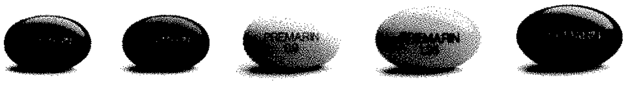
Estrogens have been reported to increase the risk of endometrial carcinoma in postmenopausal women. Estrogens should not be used in women (or men) with any of the following conditions: known or suspected 1) pregnancy, 2) breast cancer, 3) estrogen-dependent neoplasia, 4) undiagnosed abnormal genital bleeding, 5) active thrombophlebitis or thromboembolic disorders.

See important information on adjacent page.

For moderate-to-severe vasomotor symptoms and for osteoporosis

PREMARIN®

(conjugated estrogens tablets)



0.3 mg 0.625 mg 0.9 mg 1.25 mg 2.5 mg

The appearance of these tablets is a trademark of Wyeth-Ayerst Laboratories.

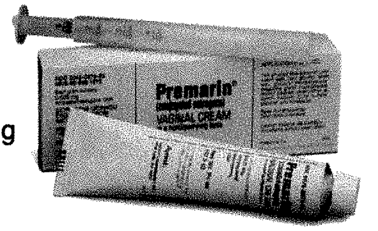
For atrophic vaginitis

PREMARIN®

(conjugated estrogens)

Vaginal Cream

0.625 mg/g



BRIEF SUMMARY *(FOR FULL PRESCRIBING INFORMATION AND PATIENT INFORMATION, SEE PACKAGE CIRCULARS.)*

PREMARIN® Brand of conjugated estrogens tablets, USP
PREMARIN® Brand of conjugated estrogens Vaginal Cream, in a nonliquefying base

1. ESTROGENS HAVE BEEN REPORTED TO INCREASE THE RISK OF ENDOMETRIAL CARCINOMA.
Close clinical surveillance of all women taking estrogens is important. Adequate diagnostic measures including endometrial sampling when indicated should be undertaken to rule out malignancy in all cases of undiagnosed persistent or recurring abnormal vaginal bleeding. There is currently no evidence that "natural" estrogens are more or less hazardous than "synthetic" estrogens at equiestrogenic doses.
2. ESTROGENS SHOULD NOT BE USED DURING PREGNANCY.
Estrogen therapy during pregnancy is associated with an increased risk of congenital defects in the reproductive organs of the male and female fetus, an increased risk of vaginal adenosis, squamous-cell dysplasia of the uterine cervix, and vaginal cancer in the female later in life. The 1985 DES Task Force concluded that women who used DES during their pregnancies may subsequently experience an increased risk of breast cancer. However, a causal relationship is still unproven, and the observed level of risk is similar to that for a number of other breast cancer risk factors.

There is no indication for estrogen therapy during pregnancy. Estrogens are ineffective for the prevention or treatment of threatened or habitual abortion.

DESCRIPTION: PREMARIN (conjugated estrogens, USP) contains a mixture of estrogens, obtained exclusively from natural sources, blended to represent the average composition of material derived from pregnant mares' urine. It contains estrone, equilin, and 17α-dihydroequilin, together with smaller amounts of 17α-estradiol, equilenin, and 17α-dihydroequilenin as salts of their sulfate esters. Tablets are available in 0.3 mg, 0.625 mg, 0.9 mg, 1.25 mg, and 2.5 mg strengths of conjugated estrogens. Cream is available as 0.625 mg conjugated estrogens per gram.

INDICATIONS AND USAGE: Moderate-to-severe vasomotor symptoms associated with the menopause. (There is no evidence that estrogens are effective for nervous symptoms or depression which might occur during menopause and they should not be used to treat these conditions.) Prevention and management of osteoporosis (abnormally low bone mass). Atrophic vaginitis. Atrophic urethritis. Hypoestrogenism due to hypogonadism, castration or primary ovarian failure.

PREMARIN (conjugated estrogens) Vaginal Cream is indicated in the treatment of atrophic vaginitis and kraurosis vulvae.

PREMARIN HAS NOT BEEN SHOWN TO BE EFFECTIVE FOR ANY PURPOSE DURING PREGNANCY AND ITS USE MAY CAUSE SEVERE HARM TO THE FETUS (SEE BOXED WARNING).

CONTRAINDICATIONS: Estrogens should not be used in women (or men) with any of the following conditions: 1. Known or suspected pregnancy (see Boxed Warning). 2. Known or suspected cancer of the breast except in appropriately selected patients being treated for metastatic disease. 3. Known or suspected estrogen-dependent neoplasia. 4. Undiagnosed abnormal genital bleeding. 5. Active thrombophlebitis or thromboembolic disorders. 6. Estrogen replacement therapy has not been reported to increase the risk of thrombophlebitis and/or thromboembolic disease. However, there is insufficient information regarding women who have had previous thromboembolic disease.

PREMARIN Tablets and Vaginal Cream should not be used in patients hypersensitive to their ingredients.

WARNINGS: Some studies suggest a possible increased incidence of breast cancer in women taking higher doses of estrogen for prolonged time periods. The majority of studies have not shown an association with usual estrogen replacement doses. Endometrial cancer risk among estrogen users was about 4-fold or greater than in non-users, and appears dependent on treatment duration and estrogen dose. In patients on combined estrogen-progestin therapy, this risk appears to be decreased. (See PRECAUTIONS below.)

Estrogen therapy during pregnancy is associated with an increased risk of fetal congenital reproductive tract disorders.

A 2.5-fold increase in the risk of surgically confirmed gall bladder disease in women receiving postmenopausal estrogens has been reported.

Large doses of estrogen such as those used to treat prostate and breast cancer have been shown to increase the risk of non-fatal myocardial infarction, pulmonary embolism, and thrombophlebitis in men. This cannot necessarily be extrapolated to women. However, to avoid theoretical cardiovascular risk caused by high estrogen doses, the doses for estrogen replacement therapy should not exceed the recommended dose.

Blood pressure should be monitored with estrogen use, especially if high doses are used.

Estrogens may lead to severe hypercalcemia in patients with breast cancer and bone metastases.

PRECAUTIONS: The addition of a progestin for 7 or more days of a cycle of estrogen administration reportedly lowers the incidence of endometrial hyperplasia. Studies of endometrium suggest that 10 to 13 days of progestin are needed to provide maximal endometrial maturation and elimination of hyperplastic changes. Additional risk, such as adverse effects on carbohydrate and lipid metabolism, may be associated with the inclusion of progestin in estrogen replacement regimens. The choice of progestin and dosage may be important in minimizing these adverse effects.

Physical examination and a complete medical and family history should be taken prior to the initiation of any estrogen therapy with special reference to blood pressure, breasts, abdomen, and pelvic organs, and should include a Papanicolaou smear. As a general rule, estrogen should not be prescribed for longer than one yea without another physical examination being performed. Conditions influenced by fluid retention, such as asthma, epilepsy, migraine, and cardiac or renal dysfunction, require careful observation. Certain patients may develo manifestations of excessive estrogenic stimulation, such as abnormal or excessive uterine bleeding an mastodynia. Pre-existing uterine leiomyomata may increase in size during estrogen use. Estrogens should b used with care in patients with impaired liver function, renal insufficiency, or metabolic bone diseases associate with hypercalcemia.

The following drug/laboratory test interactions have been reported, some only with estrogen-progesti combinations (oral contraceptives):

1. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability.
2. Increased thyroid binding globulin (TBG) leading to increased circulating total thyroid hormone, a measured by T_4 levels determined by column or by radioimmunoassay. Free T_3 resin uptake is decreased reflecting the elevated TBG; free T_4 concentration is unaltered.
3. Impaired glucose tolerance.
4. Reduced response to metyrapone test.
5. Reduced serum folate concentration.

MUTAGENESIS AND CARCINOGENESIS: Long-term, continuous administration of natural and synthet estrogens in certain animal species increases the frequency of carcinomas of the breast, cervix, vagina, and liver

PREGNANCY CATEGORY X: Estrogens should not be used during pregnancy. See **CONTRAINDICATION** and Boxed Warning.

NURSING MOTHERS: As a general principle, the administration of any drug to nursing mothers should be don only when clearly necessary since many drugs are excreted in human milk.

ADVERSE REACTIONS: The following have been reported with estrogenic therapy; changes in vaginal bleedin pattern and abnormal withdrawal bleeding or flow, breakthrough bleeding, spotting, increase in size of uterin fibromyomata, vaginal candidiasis, change in amount of cervical secretion; tenderness or enlargement of breasts nausea, vomiting, abdominal cramps, bloating, cholestatic jaundice; chloasma or melasma that may persist whe drug is discontinued, erythema multiforme, erythema nodosum, hemorrhagic eruption, loss of scalp hai hirsutism; steepening of corneal curvature, intolerance to contact lenses; headache, migraine, dizziness, menta depression, chorea; increase or decrease in weight; reduced carbohydrate tolerance; aggravation of porphyria edema; changes in libido.

ACUTE OVERDOSAGE: May cause nausea and vomiting.

DOSAGE AND ADMINISTRATION:

PREMARIN® Brand of conjugated estrogens tablets, USP

1. *Given cyclically for short-term use only.* For treatment of moderate-to-severe vasomotor symptoms, atroph vaginitis, or atrophic urethritis associated with the menopause (0.3 mg to 1.25 mg or more daily). The lowest dos that will control symptoms should be chosen and medication should be discontinued as promptly as possible Administration should be cyclic (eg, three weeks on and one week off). Attempts to discontinue or tape medication should be made at three- to six-month intervals.
2. *Given cyclically:* Hypoestrogenism. Osteoporosis.

Hypoestrogenism due to: Female hypogonadism—2.5 mg to 7.5 mg daily in divided doses for 20 day followed by 10 day rest period. If bleeding does not occur by the end of this period, the same dosage schedule i repeated. Female castration or primary ovarian failure—1.25 mg daily, cyclically. Adjust upward or downwar according to response of the patient. For maintenance, adjust dosage to lowest level that will provide effectiv control.

Osteoporosis—0.625 mg daily. Administration should be cyclic (eg, three weeks on and one week off).

PREMARIN® Brand of conjugated estrogens Vaginal Cream

Given cyclically for short-term use only. For treatment of atrophic vaginitis or kraurosis vulvae.

The lowest dose that will control symptoms should be chosen and medication should be discontinued a promptly as possible.

Attempts to discontinue or taper medication should be made at three- to six-month intervals.

Usual dosage range: 2 g to 4 g daily, intravaginally, depending on the severity of the condition.

Patients with an intact uterus who are treated with either PREMARIN Tablets or Vaginal Cream should b monitored for signs of endometrial cancer and appropriate measures taken to rule out malignancy in the event o persistent or recurring abnormal vaginal bleeding.

Revised August 21, 198

INFORMATION FOR AUTHORS

Editorial policies

The requirements for manuscripts submitted to the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY conform to the "Uniform Requirements for Manuscripts Submitted to Biomedical Journals" established by the International Committee of Medical Journal Editors and published in *Annals of Internal Medicine* 1988;108:258-65. Certain requirements unique to our JOURNAL are provided in Information for Authors, published in each issue of the JOURNAL.

Manuscript submission. Manuscripts should be submitted to one of the two Editors in Chief as follows:

1. **Dr. Zuspan**—manuscripts from the eastern United States and from England, Israel, and Italy, manuscripts written for Clinical Opinion and Current Development, Letters to the Editors, and all manuscripts presented before one of the official sponsoring societies, except the Society for Gynecologic Investigation. *Manuscripts from The Society of Perinatal Obstetricians should be submitted to Dr. Donald R. Coustan, Department of Obstetrics and Gynecology, Women and Infants Hospital of Rhode Island, 101 Dudley St., Providence, RI 02905.*
2. **Dr. Quilligan**—manuscripts from states west of Pennsylvania, West Virginia, Kentucky, Tennessee, and Mississippi; manuscripts from Hawaii, Alaska, Canada, and abroad (except England, Israel, and Italy). Dr. Quilligan is responsible for manuscripts from the Society for Gynecologic Investigation. *Manuscripts from the Society for Gynecologic Investigation should be submitted to Dr. Roger A. Lobo, Women's Hospital, 1240 North Mission Road, Room 1M2, Los Angeles, CA 90033.*

Author's designation of reviewers. When authors submit their manuscripts, they should provide the names and addresses of at least three reviewers for consideration by the Editors.

Copyright statement. The specified copyright statement that follows the Information for Authors in each issue of the JOURNAL must be completed, signed by all authors, and submitted with the manuscript. (The Checklist and Copyright Statement may be torn from the JOURNAL or photocopied for submission.) If not completed in full, it will be returned to the author for completion.

Checklist. The checklist that appears with the copyright statement in each issue of the JOURNAL must be fully completed by the author(s) and sent with each submitted manuscript. A more complete description of each item that must be checked is provided under the appropriate heading in the Information for Authors, which is published in each issue of the JOURNAL. *If the checklist is not completed in full, the deficiencies will be noted, and the form, as well as the manuscript when necessary, will be returned to the author for completion.*

Previous publication. If a report by the same author(s) has been previously published in any medium that deals in any respect whatever with the same patients, same animals, same laboratory experiments, or same data, in part or in full, as those reported in the manuscript being submitted, two reprints of the article or two copies of the manuscript, be it a full-length report or an abstract, must be submitted with the manuscript. The author(s) should inform the Editor of the circumstances, similarities, and differences of the reports. This requirement also applies to the submission of a manuscript in which a few different patients, animals, laboratory experiments, or data were added to those reported in a previous publication or in a submitted or accepted manuscript. Articles previously published in another language will not be considered.

Human and animal experimentation. It is assumed by the Editors that manuscripts emanating from a particular institution are submitted with the approval of the requisite authority. Human experimentation that requires local institutional approval must have this approval *before the ex-*

periment is started and approval must be so indicated in the Methods section of the submitted manuscript. Reports of experiments on animals must *state in the Methods section of the manuscript* that the guidelines for the care and use of the animals *approved by the local institution* were followed. The species of nonhuman animals used in an investigation must be named in the title, abstract, and key words of the manuscript.

Authorship. For manuscripts with two or more authors, each author must qualify by having participated actively and sufficiently in the study that is being performed and reported. The inclusion of each author in the authorship list of a report is based only (1) on substantial contributions to (a) concept and design, or analysis and interpretation of data and (b) drafting the manuscript or revising it critically for important intellectual content; and (2) on final approval by each author of the version of the manuscript. Conditions 1 (a and b) and 2 must both be met. Others contributing to the work should be recognized separately in an Acknowledgment. In the covering letter that accompanies the submitted manuscript, it must be confirmed that all authors fulfilled both conditions.

Conflict of interest. Authors are expected to inform the Editor, in a letter accompanying the submitted manuscript, of any commercial association that might pose a conflict of interest, such as ownership, stock holdings, equity interests and consultant activities, or patent-licensing situations. Such information is confidential, is not given to the consultants, and does not play a part in the decision of the quality or timeliness of the manuscript. If the manuscript is accepted, the author and the Editor will determine how best to release the information. The usual and customary listing of sources of support and institutional affiliations on the title page is proper and does not imply a conflict of interest; only where there is a possible conflict of interest is the author(s) expected to inform the Editor.

Disclaimer. Statements and opinions expressed in articles and communications herein are those of the author(s) and not necessarily those of the Editor(s) or Publisher, and the Editor(s) and Publisher disclaim any responsibility or liability for such material. Neither the Editor(s) nor the Publisher guarantees, warrants, or endorses any product or service advertised in this publication, nor do they guarantee any claim made by the manufacturer of such product or service.

General requirements for preparation of manuscripts

The original and two good-quality photocopies of the manuscript and three sets of glossy prints of illustrations are required.

Manuscripts must be typed double-spaced on one side only of 22 × 28 cm (8½ × 11 inch) white bond paper with 1-inch margins at top, bottom, and sides. Number pages consecutively in the upper right-hand corner in the following order: title page, condensation, abstract, body of text, acknowledgments, references, figure legends, and tables.

Title page. The title page (page 1) should contain in sequence the title (concise and suitable for indexing purposes); author line with first name, middle initial, and last name of each author and each author's highest academic degree (both MD and PhD are acceptable, but honors degrees are not permitted); city(ies), state(s) in which the study was conducted; divisional, or departmental, and institutional affiliations at the time the study was performed; source(s) of financial support; presented line, if applicable; disclaimers, if any; name, address, business and home telephone numbers, and fax number of author to whom requests for reprints should be addressed (if reprints will not be available, it should be so stated); and name, address, business and home telephone numbers, and fax number of author responsible for correspondence concerning the manuscript if different from author to whom reprint requests are addressed. At the bottom of the title page supply a short title for the running head not exceeding 52 characters (including word spaces).

Condensation. On page 2 of the manuscript provide a brief, concise condensation, typed double-spaced, that will appear with the title in publication of the Contents pages of the JOURNAL. It should be a single-spaced sentence, limited to a maximum of 25 words, delineating the essential point(s) made in the manuscript.

Abstract page and key words/phrases. On manuscript page 3, type the abstract, double-spaced, with the required margins and headed by the title of the article and name(s) of author(s). Abstracts for regular articles, Current Investigation, Clinical Opinion, and Current Development may not exceed 150 words. Abstracts for case reports and brief communications may not exceed 50 words. Below the abstract list 3 to 5 *key words* or short phrases for indexing purposes.

Text. Do not hesitate to write your manuscript in the first-person, active voice if it is more appropriate to the information you wish to convey. The passive voice is generally more effective for describing techniques or observations, since the emphasis is on the "action" rather than on the person performing the action.

Only standard abbreviations are to be used. Consult the *Council of Biology Editors Style Manual* or the AMA's *Manual for Authors and Editors.* Abbreviations in the title are not acceptable. They should be avoided, if possible, in the abstract. In the text they should be kept to a practical minimum. The full term for which an abbreviation stands should precede its first use in the text unless it is a standard unit of measurement.

Either the generic, chemical, or proprietary names of drugs may be used. If the generic or chemical name is used, authors may, if they desire, insert the proprietary name in parentheses after the first mention in the text, with the name of the manufacturer and city and state.

Regular articles are customarily organized into the following sections: an introduction and headings that identify Material and Methods, Results, and Comment. Authors may wish to summarize their findings in a short paragraph at the end of the Comment section. This format may not be appropriate for some types of articles.

In the introduction, state concisely the purpose and rationale for the study and cite only the most pertinent references as background.

In the *Material and Methods* section describe briefly (but in sufficient detail to permit other workers to evaluate and reproduce the results) the plan, patients and/or experimental animals and controls, methods and procedures utilized, and statistical method(s) employed.

In the *Results* section present the detailed findings. Include mentions of all tables and/or figures. Figures and tables should supplement, not duplicate, the text; presentation of data in either one or the other will suffice. Emphasize only your important observations; do not compare

Estimating length of manuscripts

With the exception of Current Development articles, the length of text material (introduction through Comment section) in regular manuscripts accepted for publication normally ranges from 750 to 4200 words (an average of 2000 words). A text of 4200 words or more can seldom be accepted, especially if tables and figures are included. The average manuscript of 2000 words of text with abstract, 3 tables with captions, 2 figures with legends, and references makes a 5.7-page article in the JOURNAL. The 2000 words of text alone makes approximately 8 pages of manuscript typed double-spaced with the required 1-inch margins (approximately 250 words per page). A table or figure that occupies both columns of half a JOURNAL page is equivalent to approximately 500 words in manuscript. Thus, if a greater number of illustrations and tables is used, the length of the text should be adjusted accordingly.

your observations with those of others. Such comparisons and comments are reserved for the Comment section.

In the *Comment* section state the importance and significance of your findings but do not repeat the details given in the Results section. Limit your opinions to those strictly indicated by the facts in your report. Compare your findings with those of others. No new data should be presented in this section.

Acknowledgments. Acknowledge only persons who have made substantive contributions to the study.

References. A reasonable number (25) is allowed, except in case reports and brief communications (limited to 2) and in manuscripts for the Current Development section (for which there is no limit). Number references consecutively in the order in which they are mentioned in the text. Use the format of the "Uniform Requirements for Manuscripts Submitted to Biomedical Journals" (Vancouver style) (Ann Intern Med 1988;108:258-65). Journal titles should conform to abbreviations used in *Cumulated Index Medicus.*

Examples (if six or fewer authors, list all; if seven or more authors, list three then et al.):

JOURNAL: Flamm BL, Dunnett C, Fischermann E, Quilligan EJ. Vaginal delivery following cesarean section: use of oxytocin augmentation and epidural anesthesia with internal tocodynamic and internal fetal monitoring. AM J OBSTET GYNECOL 1984;148:759-63.

BOOKS: Ledger WJ. Dystocia and prolonged labor. In: Wilson JR, Carrington ER, eds. Obstetrics and gynecology. St. Louis: CV Mosby, 1987 vol 8:474-93.

Personal communications and unpublished data, if essential, may be used but not as numbered references. If they are used, they are to be referred to, within parentheses, at the appropriate location in the text. If used, the author(s) must obtain written and signed permission for their use from the individual being quoted. This signed permission must accompany the manuscript when it is submitted to the Editor. Published abstracts can be used as numbered references; however, reference to the complete published article is preferred.

Figures. The term *figure* includes all types of illustrations such as graphs, diagrams, photographs, flow charts, and line drawings. A reasonable number of figures will be reproduced without charge, but special arrangements must be made with the Editors for color figures at an additional charge to the author. The quoted charge is per page of color, and as many as eight color figures can be included on one page.

Figures must be cited consecutively in the text in Arabic numerals and identified with a gummed label on the back of the figure with author(s) name(s), title of article, figure number, and top marked clearly. Consistency in size within the article is strongly preferred. Any special instructions regarding sizing should be clearly noted. Do not use paper clips or mar the surface of figures in any way. Figures will be returned only on request by the author.

For *black-and-white figures,* submit three sets of 3 × 4 inch (minimum) to 5 × 7 inch (maximum) unmounted, glossy prints. All lettering must be done with commercially available paste-on letters (or numbers) or by a professional; typed or freehand lettering is not acceptable. All lettering must be in proportion to the drawing, graph, or photograph. Original drawings, appropriately done in black India ink, roentgenograms, and other material must be submitted as glossy prints with good black-and-white contrast.

For *color figures* submit original transparencies and two sets of unmounted prints on glossy (smooth surface) paper. Polaroid prints are not acceptable. Color transparencies must have a color balance (consistency in lighting and film speed) that is acceptable to the author and Editors before acceptance for publication. Please note that 35 mm transparencies are enlarged to twice their original size. If it is important to deviate from this standard, please so indicate when the material is submitted. The top, first author's last name, and figure number must be indicated on the front of each transparency and the back of each print.

Computer-generated figures must be legible and clearly printed in jet black ink on heavy coated paper with either a glossy or dull finish. Any patterns or shadings must be dark enough for reproduction and must be distinguishable from each other. Lines, symbols, and letters should be both smooth and complete. The legend should not appear on the figure. On the back of each figure the name of the first author and the figure number should be given and the top indicated. Three original individual laser or plotter prints are to be submitted *unmounted* with the manuscript. Laser prints should be full size at 300 dots per inch (DPI) or greater full-page resolution; multiple illustrations on a page cannot be accepted. Dot matrix prints and photographic halftones are not acceptable. *Color figures* are acceptable, but special arrangements must be made with the Editors. The colors used must be dark enough and of sufficient contrast for reproduction. With the exception of fluorescent colors, all colors can be reproduced in four-color figures. The preparation and submitting of color prints should fol-

low the preceding guidelines for black-and-white computer-generated illustrations.

Legends to figures. Legends for all figures must be typed double-spaced on paper separate from the text of the manuscript, and these pages must be numbered in sequence after the references. Titles should be included in the legend, not on the print. Original magnifications should be provided. If a figure has been taken from copyrighted material, the legend must give full credit to the original source.

Tables. Tables should be typed on separate sheets of paper, one table to a page, and included at the end of the text. They should be numbered in Roman numerals. Each table must be cited in sequence at an appropriate point in the text. Titles should be brief yet indicate clearly the purpose or content of each table, and each column should be precisely defined by headings. Abbreviations and special designations should be explained in a footnote to the table. If a table or any part thereof has been taken from copyrighted material, a footnote to the table must give full credit to the original source. Special arrangements must be made with the Editors for elaborate tables because of space limitations.

Permissions. Direct quotations, tables, or figures that have appeared in copyrighted material must be accompanied by written permission for their use from the copyright owner and original author along with complete information as to source. Photographs of identifiable persons must be accompanied by signed releases. If not, all recognizable features must be masked.

Requirements for manuscripts

Case reports and brief clinical and basic science communications. Limit of 700 words, 2 references. Include abstract of 50 words maximum, 3 to 5 key words/phrases for indexing purposes, and short title. If tables and/or figures are used, an equivalent number of words must be deducted from the total (see "Estimating Length of Manuscript").

Current Investigation. Same requirements as for regular article.

Clinical Opinion. Limit of 3000 words. Include abstract of 50 to 150 words, 3 to 5 key words/phrases, and short title. Submit to Dr. Zuspan.

Current Development. Limit of 6000 words. Include abstract of 50 to 150 words, 3 to 5 key words/phrases, and short title. Submit to Dr. Zuspan.

Letters to the Editors. Letters to the Editors must be submitted in duplicate, typed double-spaced, and the text of the manuscript must be limited to a maximum of 400 words (excluding references, name(s) and address(es) of the signer(s), and the phrase "To the Editors"). The submitted Letter to the Editors must be accompanied by a signed copyright statement. If there are two or more signers of the Letter to the Editors, one of the authors may sign the copyright statement but must add to the statement the following: "I sign for and accept responsibility for releasing this letter on behalf of any and all co-signers." These requirements apply to all types of Letters to the Editors. Letters should be sent to Dr. Zuspan.

Two types of letters will be considered for publication. (1) A Letter to the Editors commenting on an article that has appeared in the JOURNAL should be brief and directly related to the published article. The editorial staff reserves the right to shorten letters if necessary and to make minor editorial alterations without reference to the writer. Letters may be published together with a reply from the original author. If the original author does not respond, a notation indicating "Response declined" will be published. As space for letters is limited, only a selection of letters submitted may be published. (2) A brief case presentation or a short report of a pertinent observation in the form of a Letter to the Editors will be considered for publication.

Announcements. Announcements of major meetings and other significant activities must be received at least 8 weeks before the desired month of publication. All announcements carry a charge of $60 U.S., and the fee must accompany the request to publish. Information will be limited to title of meeting, date, place, and an address to obtain further information. Send announcements and payment, payable to this JOURNAL, to Kay G. Goehler, Senior Manuscript Editor, Journal Editing, Mosby–Year Book, Inc., 11830 Westline Industrial Drive, St. Louis, MO 63146-3318.

Books. Books received will be listed in the JOURNAL. They should be sent to Dr. Zuspan. No books will be returned.

Reprints

The corresponding author will receive a price schedule and order form at the time of publication. Reprints in quantities must be ordered from the Publisher with the author's consent.

Business communications

Communications of a business nature and all advertising communications should be addressed to: Journal Publisher, Mosby–Year Book, Inc., 11830 Westline Industrial Drive, St. Louis, MO 63146-3318, or call Journal Advertising Production Manager (314) 872-8370.

CHECKLIST AND COPYRIGHT STATEMENT

Both the checklist and the copyright statement forms **must be completed** and sent with each submitted manuscript. If **not** completed, these forms will be returned to the author for completion.

These items appear in each monthly issue of the JOURNAL. A photocopy may be used. An exposition of the requirements given in the checklist is in the Information for Authors, which is published in each issue of the JOURNAL.

CHECKLIST

General

—The original and two copies of the manuscript are submitted.

—The appropriate signed completed checklist and assignment of copyright signed by **all** authors accompany the manuscript.

—Three sets of unmounted glossy prints for regular figures are submitted, properly numbered and labeled on the back of each print.

—Three sets of original computer-generated figures printed on heavy coated paper with either a glossy or dull finish, unmounted, each one on a page, and properly labeled on the back are submitted. None are dot matrix or photographic prints.

—Human experimentation has been approved by the local institution as stated in the Methods section.

—Guidelines for the care and use of animals approved by the institution have been followed as indicated in the Methods section.

—The covering letter with essential information is with the manuscript.

—All elements of the manuscript are typed double-spaced on bond paper with 1-inch margins at top, bottom, and sides.

—All pages are numbered in the following order: title page, condensation, abstract, body of the text, acknowledgments only of persons who have made substantive contributions to the study, references, legends, and tables.

—Signed, written permission from both the copyright holder and the original author for the use of tables, figures, or quotations previously published and their complete references are enclosed with the manuscript.

—Signed, written permission for the use of quotations of personal communications and unpublished data has been obtained from the person(s) being quoted and is enclosed.

Authorship

—In the covering letter that accompanies the submitted manuscript I/we have confirmed that all authors fulfilled both conditions required for authorship.

Conflict of interest

—In the covering letter that accompanies the submitted manuscript the commercial association of the author or of any co-authors that might pose a conflict of interest is described.

Previous publications

—Enclosed with the submitted manuscript are two reprints each of articles the author or co-authors have previously published or have in manuscript form dealing with same patients, same animals, same laboratory experiment, or same data, in part or in full, as those reported in the submitted manuscript. Further explanation is provided in the covering letter that accompanies the submitted manuscript.

—Similarities and differences are identified.

Reviewers

—Names and addresses of three individuals are enclosed.

Title page

—These elements are given in the following sequence, and are typed double-spaced.

—Title.

—Author(s) name(s) and highest academic degree(s) are shown.

—City(ies), state(s), and country other than U.S. in which the study was conducted are given.

—The name(s) of the institution(s) section(s), division(s), department(s) in which the study was performed is provided and the author(s) institutional affiliation at the time of the study is indicated.

—Acknowledgment of financial support is cited.

—Name, address, business and home telephone numbers, and fax number of author to whom requests for reprints are to be sent are included.

—If reprints will not be available, this has been stated on the title page.

—If the corresponding author is different from the author to whom reprint requests are to be sent, his/her name, address, business and home telephone numbers, and fax number have been added.

—At the bottom of the page, a running head not exceeding 52 characters (including word spaces) has been typed.

Condensation

—On a separate sheet of paper, page 2 of the manuscript, a single sentence limited to 25 words delineating the essential point(s) is typed double-spaced.

Abstract

—The abstract is typed double-spaced with required margins (on page 3) headed by the title and the author(s) name, not exceeding 150 words. For case reports and brief communications the limit of 50 words is not exceeded.

—Three to five key words or short phrases are placed beneath the abstract on page 3.

Tables

- —Each table headed by a title and numbered in Roman numerals is typed double-spaced on a separate page.
- —Tables are cited in sequence in the text.

Figures

- —Each is numbered with an Arabic numeral and cited in numerical sequence in the text.
- —Original transparencies of **color photographs** appropriately numbered and identified are submitted along with two sets of unmounted prints on glossy paper, numbered and identified on the back.

References

- —Are typed double-spaced.
- —Are numbered consecutively in the order they are cited in the text.
- —The format of the "Uniform Requirements for Manuscripts Submitted to Biomedical Journals" is used. Examples shown in Information for Authors were followed.
- —Personal communications and unpublished observations are not used as numbered references but are mentioned in the text with the written approval of the person being quoted. The signed approval is enclosed.

AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY

COPYRIGHT STATEMENT

Must be signed by ALL authors

"The undersigned author(s) transfers all copyright ownership of the manuscript entitled

to Mosby–Year Book, Inc., in the event the work is published. The undersigned author(s) warrants that the article is original; is not under consideration by another publication; and its essential substance, tables, or figures have not been previously published. This restriction does not apply to abstracts or press reports published in connection with scientific meetings. The author(s) confirms the final manuscript has been read and each author's contribution has been approved by the appropriate author."

The responsible author(s) must be named____________________ ____________________

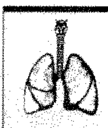
DRUG ABUSE
IS CHILD ABUS

The effects of cocaine abuse have been directly linked to certain congenital anomalies in infants, including intestinal atresia, limb reductions, and brain disruptions. These infants are also at a greater risk for congenital heart, urinary tract, and genitourinary defects.



Approximately 80% of the offspring of heroin-dependent women who receive no prenatal care experience serious medical problems such as intracranial hemorrhages and respiratory distress syndrome.

Neonates exposed to cocaine in utero have been documented to experience neurobehavioral abnormalities. They tend to be irritable and easily overstimulated.

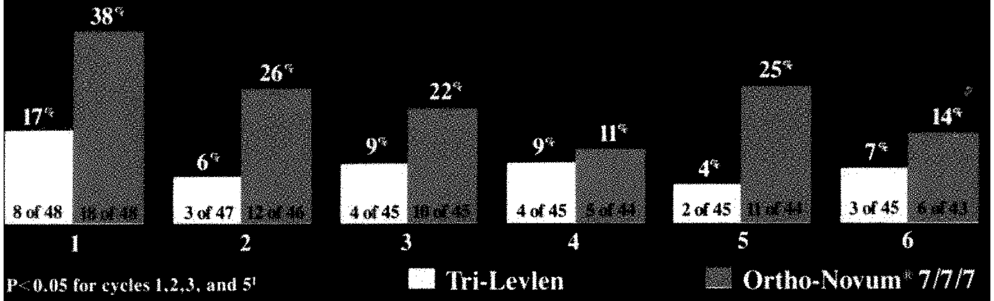
Tri-Levlen means a low incidence of breakthrough bleeding/spotting*†

Multicenter study demonstrates significantly less breakthrough bleeding/spotting through the first six cycles[1]



n = number of women with a bleeding event occurring during a cycle.

TRI·LEVLEN®

Levonorgestrel and ethinyl estradiol tablets · Triphasic regimen

may mean a lot to a woman

---

* Incidence defined as percentage of women with a bleeding event occurring at least once during a pill cycle. Serious as well as minor side effects have been reported with the use of oral contraceptives. The physician should remain alert to the earliest symptoms of serious disease and discontinue oral contraceptive therapy when appropriate. Please see full prescribing information, a brief summary of which follows.

† Defined as intermenstrual bleeding.

Ortho-Novum® is a registered trademark of Ortho Pharmaceutical Corp.

BERLEX Dedicated to innovation in OB/GYN medicine

TRI·LEVLEN® Levonorgestrel and ethinyl estradiol tablets–Triphasic regimen

TRI-LEVLEN® 28 TRI-LEVLEN® 21

BRIEF SUMMARY

Tri-Levlen®—6 brown tablets, each containing 0.050 mg of levonorgestrel (d(-)-13 beta-ethyl-17-alpha-ethinyl-17-beta-hydroxygon-4-en-3-one), a totally synthetic progestogen, and 0.030 mg of ethinyl estradiol (19-nor-17α-pregna-1,3,5(10)-trien-20-yne-3, 17-diol); 5 white tablets, each containing 0.075 mg levonorgestrel and 0.040 mg ethinyl estradiol; 10 light-yellow tablets, each containing 0.125 mg levonorgestrel and 0.030 mg ethinyl estradiol (7 light-green tablets containing inert ingredients are included in the 28-day triphasic regimen).

Indications and Usage

Oral contraceptives are indicated for the prevention of pregnancy in women who elect to use this product as a method of contraception.

Contraindications

Oral contraceptives should not be used in women with any of the following conditions: thrombophlebitis or thromboembolic disorders, a past history of deep-vein thrombophlebitis or thromboembolic disorders, cerebral-vascular or coronary-artery disease, known or suspected carcinoma of the breast, carcinoma of the endometrium or other known or suspected estrogen-dependant neoplasia, undiagnosed abnormal genital bleeding, cholestatic jaundice of pregnancy or jaundice with prior pill use, hepatic adenomas or carcinomas, known or suspected pregnancy.

Warnings

Cigarette smoking increases the risk of serious cardiovascular side effects from oral-contraceptive use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use oral contraceptives should be strongly advised not to smoke.

The use of oral contraceptives is associated with increased risks of several serious conditions including myocardial infarction, thromboembolism, stroke, hepatic neoplasia, gallbladder disease, and hypertension, although the risk of serious morbidity or mortality is very small in healthy women without underlying risk factors. The risk of morbidity and mortality increases significantly in the presence of other underlying risk factors such as hypertension, hyperlipidemias, obesity and diabetes. Practitioners prescribing oral contraceptives should be familiar with the following information relating to these risks. The information contained in this package insert is principally based on studies carried out in patients who used oral contraceptives with higher formulations of estrogens and progestogens than those in common use today. The effect of long-term use of the oral contraceptives with lower formulations of both estrogens and progestogens remains to be determined. Throughout this labeling, epidemiological studies reported are of two types: retrospective or case control studies and prospective or cohort studies. Case control studies provide a measure of the relative risk of disease, namely, a ratio of the incidence of a disease among oral-contraceptive users to that among nonusers. The relative risk does not provide information on the actual clinical occurrence of a disease. Cohort studies provide a measure of attributable risk, which is the difference in the incidence of disease between oral-contraceptive users and nonusers. The attributable risk does provide information about the actual occurrence of a disease in the population. For further information, the reader is referred to a text on epidemiological methods.

1. *Thromboembolic Disorders and Other Vascular Problems*

a. *Myocardial Infarction.* An increased risk of myocardial infarction has been attributed to oral-contraceptive use. This risk is primarily in smokers or women with other underlying risk factors for coronary-artery disease such as hypertension, hypercholesterolemia, morbid obesity, and diabetes. The relative risk of heart attack for current oral-contraceptive users has been estimated to be two to six. The risk is very low under the age of 30. Smoking in combination with oral-contraceptive use has been shown to contribute substantially to the incidence of myocardial infarctions in women in their mid-thirties or older with smoking accounting for the majority of excess cases. Mortality rates associated with circulatory disease have been shown to increase substantially in smokers over the age of 35 and non-smokers over the age of 40 among women who use oral contraceptives. Oral contraceptives may compound the effects of well-known risk factors, such as hypertension, diabetes, hyperlipidemias, age and obesity. In particular, some progestogens are known to decrease HDL cholesterol and cause glucose intolerance, while estrogens may create a state of hyperinsulinism. Oral contraceptives have been shown to increase blood pressure among users (see section 9 in "Warnings"). Similar effects on risk factors have been associated with an increased risk of heart disease. Oral contraceptives must be used with caution in women with cardiovascular disease risk factors

b. *Thromboembolism.* An increased risk of thromboembolic and thrombotic disease associated with the use of oral contraceptives is well established. Case control studies have found the relative risk of users compared to nonusers to be 3 for the first episode of superficial venous thrombosis, 4 to 11 for deep-vein thrombosis or pulmonary embolism, and 1.5 to 6 for women with predisposing conditions for venous thromboembolic disease. Cohort studies have shown the relative risk to be somewhat lower, about 3 for new cases and about 4.5 for new cases requiring hospitalization. The risk of thromboembolic disease due to oral contraceptives is not related to length of use and disappears after pill use is stopped. A two-to four-fold increase in relative risk of postoperative thromboembolic complications has been reported with the use of oral contraceptives. The relative risk of venous thrombosis in women who have predisposing conditions is twice that of women without such medical conditions. If feasible, oral contraceptives should be discontinued at least four weeks prior to and for two weeks after elective surgery of a type associated with an increase in risk of thromboembolism and during and following prolonged immobilization. Since the immediate post partum period is also associated with an increased risk of thromboembolism, oral contraceptives should be started no earlier than four to six weeks after delivery in women who elect not to breast-feed, or a midtrimester pregnancy termination.

c. *Cerebrovascular diseases.* Oral contraceptives have been shown to increase both the relative and attributable risks of cerebrovascular events (thrombotic and hemorrhagic strokes), although, in general, the risk is greatest among older (>35 years), hypertensive women who also smoke. Hypertension was found to be a risk factor for both users and nonusers, for both types of strokes, while smoking interacted to increase the risk for hemorrhagic strokes. In a large study, the relative risk of thrombotic strokes has been shown to range from 3 for normotensive users to 14 for users with severe hypertension. The relative risk of hemorrhagic stroke is reported to be 1.2 for nonsmokers who used oral contraceptives, 2.6 for smokers who did not use oral contraceptives, 7.6 for smokers who used oral contraceptives, 1.8 for normotensive users and 25.7 for users with severe hypertension. The attributable risk is also greater in older women.

d. *Dose-related risk of vascular disease from oral contraceptives.* A positive association has been observed between the amount of estrogen and progestogen in oral contraceptives and the risk of vascular disease. A decline in serum high-density lipoproteins (HDL) has been reported with many progestational agents. A decline in serum high-density lipoproteins has been associated with an increased incidence of ischemic heart disease. Because estrogens increase HDL cholesterol, the net effect of an oral contraceptive depends on a balance achieved between doses of estrogen and progestogen and the nature and absolute amount of progestogen used in the contraceptive. The amount of both hormones should be considered in the choice of an oral contraceptive. Minimizing exposure to estrogen and progestogen is in keeping with good principles of therapeutics. For any particular estrogen/progestogen combination, the dosage regimen prescribed should be one which contains the least amount of estrogen and progestogen that is compatible with a low failure rate and the needs of the individual patient. New acceptors of oral-contraceptive agents should be started on preparations containing less than 50 mcg of estrogen.

e. *Persistence of risk of vascular disease.* There are two studies which have shown persistence of risk of vascular disease for ever-users of oral contraceptives. In a study in the United States, the risk of developing myocardial infarction after discontinuing oral contraceptives persists for at least 9 years for women 40-49 years who had used oral contraceptives for five or more years, but this increased risk was not demonstrated in other age groups. In another study in Great Britain, the risk of developing cerebrovascular disease persisted for at least 6 years after discontinuation of oral contraceptives, although excess risk was very small. However, both studies were performed with oral-contraceptive formulations containing 50 micrograms or higher of estrogens.

2. *Estimates of Mortality from Contraceptive Use.* One study gathered data from a variety of sources which have estimated the mortality rate associated with different methods of contraception at different ages. These estimates include the combined risk of death associated with contraceptive methods plus the risk attributable to pregnancy in the event of method failure. Each method of contraception has its specific benefits and risks. The study concluded that with the exception of oral-contraceptive users 35 and older who smoke and 40 and older who do not smoke, mortality associated with all methods of birth control is less than that associated with childbirth. The observation of a possible increase in risk of mortality with age for oral-contraceptive users is based on data gathered in the 1970's—but not reported until 1983. However, current clinical practice involves the use of lower estrogen dose formulations combined with careful restriction of oral-contraceptive use to women who do not have the various risk factors listed in this labeling. Because of these changes in practice and, also, because of some limited new data which suggest that the risk of cardiovascular disease with the use of oral contraceptives may now be less than previously observed, the Fertility and Maternal Health Drugs Advisory Committee was asked to review the topic in 1989. The Committee concluded that although cardiovascular-disease risks may be increased with oral-contraceptive use after age 40 in healthy nonsmoking women (even with the newer low-dose formulations), there are greater potential health risks associated with pregnancy in older women and with the alternative surgical and medical procedures which may be necessary if such women do not have access to effective and acceptable means of contraception. Therefore, the Committee recommended that the benefits of oral-contraceptive use by healthy nonsmoking women over 40 may outweigh the possible risks. Of course, older women, as all women who take oral contraceptives, should take the lowest possible dose formulation that is effective.

3. *Carcinoma of the Reproductive Organs.* Numerous epidemiological studies have been performed on the incidence of breast, endometrial, ovarian and cervical cancer in women using oral contraceptives. The overwhelming evidence in the literature suggests that use of oral contraceptives is not associated with an increase in the risk of developing breast cancer, regardless of the age and parity of first use or with most of the marketed brands and doses. The Cancer and Steroid Hormone (CASH) study also showed no latent effect on the risk of breast cancer for at least a decade following long-term use. A few studies have shown a slightly increased relative risk of developing breast cancer, although the methodology of these studies, which included differences in examination of users and nonusers and differences in age at start of use, has been questioned. Some studies suggest that oral-contraceptive use has been associated with an increase in the risk of cervical intraepithelial neoplasia in some populations of women. However, there continues to be controversy about the extent to which such findings may be due to differences in sexual behavior and other factors. In spite of many studies of the relationship between oral-contraceptive use and breast and cervical cancers, a cause-and-effect relationship has not been established.

4. *Hepatic Neoplasia.* Benign hepatic adenomas are associated with oral-contraceptive use, although the incidence of benign tumors is rare in the United States. Indirect calculations have estimated the attributable risk to be in the range of 3.3 cases/100,000 for users, a risk that increases after four or more years of use. Rupture of rare, benign, hepatic adenomas may cause death through intra-abdominal hemorrhage. Studies from Britain have shown an increased risk of developing hepatocellular carcinoma in long-term (>8 years) oral-contraceptive users. However, these cancers are extremely rare in the U.S. and the attributable risk (the excess incidence) of liver cancers in oral-contraceptive users approaches less than one per million users.

5. *Ocular Lesions.* There have been clinical case reports of retinal thrombosis associated with the use of oral contraceptives. Oral contraceptives should be discontinued if there is unexplained partial or complete loss of vision; onset of proptosis or diplopia; papilledema; or retinal vascular lesions. Appropriate diagnostic and therapeutic measures should be undertaken immediately.

6. *Oral-Contraceptive Use Before or During Early Pregnancy.* Extensive epidemiological studies have revealed no increased risk of birth defects in women who have used oral contraceptives prior to pregnancy. Studies also do not suggest a teratogenic effect, particularly insofar as cardiac anomalies and limb-reduction defects are concerned, when taken inadvertently during early pregnancy. The administration of oral contraceptives to induce withdrawal bleeding should not be used as a test for pregnancy. Oral contraceptives should not be used during pregnancy to treat threatened or habitual abortion. It is recommended that for any patient who has missed two consecutive periods, pregnancy should be ruled out before continuing oral-contraceptive use. If the patient has not adhered to the prescribed schedule, the possibility of pregnancy should be considered at the time of the first missed period. Oral-contraceptive use should be discontinued if pregnancy is confirmed

7. *Gallbladder Disease.* Earlier studies have reported an increased lifetime relative risk of gallbladder surgery in users of oral contraceptives and estrogens. More recent studies, however, have shown that the relative risk of developing gallbladder disease among oral-contraceptive users may be minimal. The recent findings of minimal risk may be related to the use of oral-contraceptive formulations containing lower hormonal doses of estrogens and progestogens

8. *Carbohydrate and Lipid Metabolic Effects.* Oral contraceptives have been shown to cause glucose intolerance in a significant percentage of users. Oral contraceptives containing greater than 75 micrograms of estrogens cause hyperinsulinism, while lower doses of estrogen cause less glucose intolerance. Progestogens increase insulin secretion and create insulin resistance, this effect varying with different progestational agents. However, in the nondiabetic woman, oral contraceptives appear to have no effect on fasting blood glucose. Because of these demonstrated effects, prediabetic and diabetic women should be carefully observed while taking oral contraceptives. A small proportion of women will have persistent hypertriglyceridemia while on the pill. As discussed earlier (see "Warnings" 1a. and 1d.), changes in serum triglycerides and lipoprotein levels have been reported in oral-contraceptive users.

9. *Elevated Blood Pressure.* An increase in blood pressure has been reported in women taking oral contraceptives and this increase is more likely in older oral-contraceptive users and with continued use. Data from the Royal College of General Practitioners and subsequent randomized trials have shown that the incidence of hypertension increases with increasing quantities of progestogens. Women with a history of hypertension or hypertension-related diseases, or renal disease should be encouraged to use another method of contraception. If women with hypertension elect to use oral contraceptives, they should be monitored closely, and if significant elevation of blood pressure occurs, oral contraceptives should be discontinued. For most women, elevated blood pressure will return to normal after stopping oral contraceptives, and there is no difference in the occurrence of hypertension among ever-and never-users.

10. *Headache.* The onset or exacerbation of migraine or development of headache with a new pattern that is recurrent, persistent or severe requires discontinuation of oral contraceptives and evaluation of the cause.

11. *Bleeding Irregularities.* Breakthrough bleeding and spotting are sometimes encountered in patients on oral contraceptives, especially during the first three months of use. The type and dose of progestogen may be important. Nonhormonal causes should be considered and adequate diagnostic measures taken to rule out malignancy or pregnancy in the event of breakthrough bleeding, as in the case of any abnormal vaginal bleeding. If pathology has been excluded, time or a change to another formulation may solve the problem. In the event of amenorrhea, pregnancy should be ruled out. Some women may encounter post-pill amenorrhea or oligomenorrhea, especially when such a condition was preexistent.

Precautions

1. PHYSICAL EXAMINATION AND FOLLOW UP. A complete medical history and physical examination should be taken prior to the initiation or reinstitution of oral contraceptives and at least annually during use of oral contraceptives. These physical examinations should include special reference to blood pressure, breasts, abdomen and pelvic organs, including cervical cytology, and relevant laboratory tests. In case of undiagnosed, persistent or recurrent abnormal vaginal bleeding, appropriate diagnostic measures should be conducted to rule out malignancy. Women with a strong family history of breast cancer or who have breast nodules should be monitored with particular care. 2. LIPID DISORDERS. Women who are being treated for hyperlipidemias should be followed closely if they elect to use oral contraceptives. Some progestogens may elevate LDL levels and may render the control of hyperlipidemias more difficult. (See "Warnings" 1d.) 3. LIVER FUNCTION. If jaundice develops in any woman receiving such drugs, the medication should be discontinued. Steroid hormones may be poorly metabolized in patients with impaired liver function. 4. FLUID RETENTION. Oral contraceptives may cause some degree of fluid retention. They should be prescribed with caution, and only with careful monitoring, in patients with conditions which might be aggravated by fluid retention. 5. EMOTIONAL DISORDERS. Patients becoming significantly depressed while taking oral contraceptives should stop the medication and use an alternate method of contraception in an attempt to determine whether the symptom is drug related. Women with a history of depression should be carefully observed and the drug discontinued if depression recurs to a serious degree. 6. CONTACT LENSES. Contact-lens wearers who develop visual changes or changes in lens tolerance should be assessed by an ophthalmologist. 7. DRUG INTERACTIONS. Reduced efficacy and increased incidence of breakthrough bleeding and menstrual irregularities have been associated with concomitant use of rifampin. A similar association, though less marked, has been suggested with barbiturates, phenylbutazone, phenytoin sodium, and possibly with griseofulvin, ampicillin and tetracyclines. 8. INTERACTIONS WITH LABORATORY TESTS. Certain endocrine-and liver-function tests and blood components may be affected by oral contraceptives: a. Increased prothrombin and factors VII, VIII, IX, and X, decreased antithrombin 3; increased norepinephrine-induced platelet aggregability. b. Increased thyroid-binding globulin (TBG) leading to increased circulating total thyroid hormone, as measured by protein-bound iodine (PBI), T4 by column or by radioimmunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG, free T4 concentration is unaltered. c. Other binding proteins may be elevated in serum. d. Sex-binding globulins are increased and result in elevated levels of total circulating sex steroids and corticoids; however, free or biologically active levels remain unchanged. e. Triglycerides may be increased. f. Glucose tolerance may be decreased. g. Serum folate levels may be depressed by oral-contraceptive therapy. This may be of clinical significance if a woman becomes pregnant shortly after discontinuing oral contraceptives. 9. CARCINOGENESIS. See "Warnings" section. 10. PREGNANCY. Pregnancy Category X. See "Contraindications" and "Warnings" sections. 11. NURSING MOTHERS. Small amounts of oral-contraceptive steroids have been identified in the milk of nursing mothers and a few adverse effects on the child have been reported, including jaundice and breast enlargement. In addition, oral contraceptives given in the postpartum period may interfere with lactation by decreasing the quantity and quality of breast milk. If possible, the nursing mother should be advised not to use oral contraceptives but to use other forms of contraception until she has completely weaned her child

Information for the Patient

See Patient Labeling.

Adverse Reactions

An increased risk of the following serious adverse reactions has been associated with the use of oral contraceptives (see "Warnings" section): thrombophlebitis, arterial thromboembolism, pulmonary embolism, myocardial infarction, cerebral hemorrhage, cerebral thrombosis, hypertension, gallbladder disease, hepatic adenomas or benign liver tumors.

There is evidence of an association between the following conditions and the use of oral contraceptives, although additional confirmatory studies are needed: mesenteric thrombosis, retinal thrombosis.

The following adverse reactions have been reported in patients receiving oral contraceptives and are believed to be drug related: nausea, vomiting; gastrointestinal symptoms (such as abdominal cramps and bloating); breakthrough bleeding; spotting; change in menstrual flow; amenorrhea; temporary infertility after discontinuation of treatment; edema; melasma which may persist; breast changes: tenderness, enlargement, secretion; change in weight (increase or decrease); change in cervical erosion and secretion; diminution in lactation when given immediately postpartum; cholestatic jaundice; migraine; rash (allergic); mental depression, reduced tolerance to carbohydrates; vaginal candidiasis; change in corneal curvature (steepening); intolerance to contact lenses.

The following adverse reactions have been reported in users of oral contraceptives and the association has been neither confirmed nor refuted: congenital anomalies, premenstrual syndrome, cataracts, optic neuritis, changes in appetite, cystitis-like syndrome, headache, nervousness, dizziness, hirsutism, loss of scalp hair, erythema multiforme, cerebral-vascular disease with mitral valve prolapse, lupus-like syndromes, erythema nodosum, hemorrhagic eruption, vaginitis, porphyria, impaired renal function, hemolytic uremic syndrome, Budd-Chiari syndrome, acne, changes in libido, colitis, sickle-cell disease.

Overdosage

Serious ill effects have not been reported following acute ingestion of large doses of oral contraceptives by young children. Overdosage may cause nausea, and withdrawal bleeding may occur in females.

Noncontraceptive Health Benefits

The following noncontraceptive health benefits related to the use of oral contraceptives are supported by epidemiological studies which largely utilized oral-contraceptive formulations containing doses exceeding 0.035 mg of ethinyl estradiol or 0.05 mg of mestranol.

Effects on menses: increased menstrual cycle regularity, decreased blood loss and decreased incidence of iron-deficiency anemia, decreased incidence of dysmenorrhea.

Effects related to inhibition of ovulation: decreased incidence of functional ovarian cysts, decreased incidence of ectopic pregnancies.

Effects from long-term use: decreased incidence of fibroadenomas and fibrocystic disease of the breast, decreased incidence of acute pelvic inflammatory disease, decreased incidence of endometrial cancer, decreased incidence of ovarian cancer.

Dosage and Administration

To achieve maximum contraceptive effectiveness, TRI-LEVLEN® tablets (Levonorgestrel and Ethinyl Estradiol Tablets—Triphasic Regimen) must be taken exactly as directed and at intervals not exceeding 24 hours.

For full details on dosage and administration see prescribing information in package insert. 60627-0 5/90

Screening recommendations for gestational diabetes mellitus

Larry Cousins, MD,[a] Laxmi Baxi, MD,[b] Ronald Chez, MD,[c] Donald Coustan, MD,[d] Steven Gabbe, MD,[e] Joseph Harris, MD,[f] Mark Landon, MD,[e] David Sacks, MD,[g] and Shailini Singh, MD[h]
San Diego, Los Angeles, and Bellflower, California, New York, New York, Tampa, Florida, Providence, Rhode Island, Columbus, Ohio, and Washington, D.C.

As a result of extensive experiences in multiple centers and a review of the current literature, we conclude that a plasma glucose level obtained 1 hour after a 50 gm oral glucose challenge is the "best" gestational diabetes mellitus screening test. This universal screening is performed at least once during pregnancy. The screening threshold should be no higher than 140 mg/dl, or an unacceptable loss in sensitivity occurs. Universal screening for gestational diabetes mellitus is justified by morbidity reduction, cost, and protocol simplicity and ease. (AM J OBSTET GYNECOL 1991;165:493-6.)

Key words: Gestational diabetes, screening

Gestational diabetes mellitus is the most common metabolic complication that affects pregnant women. The frequency of gestational diabetes mellitus and its associated maternal, perinatal, and long-term morbidity emphasize the importance of an appropriate screening method. The clinician who attempts to determine how best to screen patients for gestational diabetes mellitus is confronted with conflicting information and recommendations. This article summarizes the information that forms the basis for the authors' recommendations about screening for gestational diabetes mellitus.

Significance of gestational diabetes mellitus

Gestational diabetes mellitus is defined as carbohydrate intolerance with onset or recognition during pregnancy.[1] It is important to identify a pregnant woman with gestational diabetes mellitus because gestational diabetes mellitus is common and is associated with significant metabolic alterations, increased perinatal and maternal morbidity, and exaggerated long-term morbidity among the mothers and their offspring.

Perinatal mortality is significantly increased in gestational diabetic pregnancies if the metabolic abnormality is not recognized or if it is recognized but not treated properly.[2] In addition to an increased risk of intrauterine fetal death, commonly reported perinatal morbidity associated with gestational diabetes mellitus includes an increased incidence of macrosomia, birth trauma, neonatal hypoglycemia, hyperbilirubinemia, hypocalcemia, and polycythemia.[3] Although recent studies report enviable results regarding perinatal morbidity in cases of gestational diabetes mellitus[4, 5] there is evidence that maternal and perinatal morbidity and mortality is significantly increased in women with gestational diabetes mellitus when compared with nondiabetic pregnant women.[6, 7] Short-term maternal morbidity includes an increased incidence of chronic hypertension, hydramnios, and cesarean section.[7]

Gestational diabetes mellitus also has long-term morbidity implications for the mother and her offspring. Data from human and animal studies suggest that female fetuses exposed to chronic hyperglycemia may suffer subclinical islet cell injury.[8] Women with gestational diabetes mellitus have an increased likelihood of remaining carbohydrate intolerant after pregnancy,[9] a significantly increased risk of type II (non-insulin-dependent) diabetes later in life, and a predisposition to

6/1/29992

obesity, hyperlipidemia, atherosclerotic vascular disease, and increased systolic blood pressure and mortality.[10] The offspring of women with gestational diabetes mellitus have a higher incidence of childhood obesity,[11] type II diabetes during childhood and later in life,[11] and intellectual and motor impairment.[12]

Screening methods for gestational diabetes mellitus

A variety of methods have been proposed to screen for gestational diabetes mellitus. The Second International Workshop-Conference recommended screening with a 50 gm oral glucose load followed 1 hour later by a glucose determination in blood.[1] A recent survey has confirmed that the 1-hour oral 50 gm glucose challenge is the preferred method of screening for gestational diabetes mellitus.[13] Ninety-six percent of maternal-fetal medicine subspecialists and 84% of fellows of the American College of Obstetricians and Gynecologists (ACOG) use this method in their practice. The 50 gm oral glucose load may be administered to patients in the fasting or fed state.[14]

A 1-hour period is more efficient for screening than a 2-hour window, but it has been suggested that a 2-hour blood determination may improve specificity.[15] A 2-hour postprandial plasma glucose level has been suggested for screening nonpregnant individuals for diabetes. Random blood glucose screening seems desirable because it does not inconvenience patients and might be more cost-efficient. Lind[16] has determined 99% cutoff values of 100 mg/dl within 2 hours of a meal compared with 101 mg/dl >2 hours after a meal. However, few women with gestational diabetes mellitus have been identified by means of 2-hour postprandial or random glucose levels, so that appropriate cutoff values have not been established; therefore it has not been possible to determine the clinical utility of these methods. Glycosylated serum protein levels have been correlated with glycemic control in nonpregnant individuals, which led investigators to examine whether such tests might be effective in screening for gestational diabetes mellitus. Glycosylated hemoglobin measurements have been most studied, and they do not appear to be helpful in the detection of gestational diabetes mellitus.[17] When compared with glycosylated hemoglobin levels, the 1-hour 50 gm glucose challenge had greater specificity, sensitivity, and predictive value for a positive diagnosis.[17] Similarly, neither glycosylated albumin nor protein[18] has been of value in the diagnosis of gestational diabetes mellitus.

In view of the preceding information we recommend screening for gestational diabetes with a plasma glucose level 1 hour after a 50 gm oral glucose load.

Sensitivity and specificity considerations

An ideal screening test should have high sensitivity (proportion of cases with the disease under consideration correctly identified) and high specificity (proportion of patients without the disease correctly identified).

The choice of a threshold for screening is based on the degree of sensitivity desired and the amount of specificity to be sacrificed. In gestational diabetes mellitus this translates into the number of 3-hour 100 gm oral glucose tolerance tests one is willing to perform to detect a given proportion of gestational diabetes mellitus cases in the population. To accurately assess these test functions an ideal study would include both the screening test and the gold standard diagnostic test on all subjects. Only the study of O'Sullivan et al.[19] fulfills these criteria. In that study of 752 pregnant women, a venous whole-blood glucose level >130 mg/dl that was obtained 1 hour after a 50 gm glucose challenge was 79% sensitive and 87% specific for gestational diabetes mellitus. In a population-based study of 6214 pregnant women[20] evaluated by venous plasma and the hexokinase method of glucose analysis, the diagnostic test was performed if the 50 gm 1-hour screening value was >130 mg/dl. Although it is possible that cases of gestational diabetes went undetected because of screening values <130 mg/dl, it was assumed that sensitivity was 100% at this level. If a screening test threshold of 140 mg/dl had been used, 10% of cases would have been missed (90% sensitivity). Similar results have been reported by other investigators,[21] who also noted that gestational diabetic women with screening test values between 130 and 139 mg/dl were at significant risk for maternal hyperglycemia and neonatal hypoglycemia and macrosomia. If these data[20] are used, 14% of pregnant women would require a 3-hour oral glucose tolerance test (86% specificity) to achieve 90% sensitivity, although in both of the studies cited earlier[20, 21] 23% would require oral glucose tolerance tests (77% specificity) to achieve 100% sensitivity. Thus the obstetrician is faced with the choice of whether to use a threshold of 140 mg/dl and miss the diagnosis in 10% of the women with gestational diabetes to perform oral glucose tolerance tests on only 14% of the pregnant population or to use a threshold of 130 mg/dl and detect nearly all of the cases of gestational diabetes but perform oral glucose tolerance tests in 23% of the pregnant population. Making such a decision requires consideration of available economic resources and laboratory logistics.

As a result of this information, we recommend the use of a screening threshold no higher than 140 mg/dl.

Cost-effectiveness considerations

It is worthwhile to consider the cost of screening protocols for gestational diabetes mellitus. Although the morbidity implications and potential benefits of diagnosing gestational diabetes mellitus have been discussed previously, it is difficult (if not impossible) to allocate a dollar value to these variables. For this reason most investigators have started with this assumption made by the ACOG, the American Diabetes Association, and other groups: There are benefits for patients in whom gestational diabetes mellitus is diagnosed. Reports have focused on the relative cost of diagnosing gestational diabetes mellitus in various segments of the obstetric population. Because the prevalence of gestational diabetes mellitus increases with advancing maternal age[19, 20] and because the presence of other risk factors increases the likelihood of gestational diabetes mellitus, age and other risk factors are considered when patients are selected for screening.[22] Although one study demonstrated a similar cost per case diagnosed among patients with or without risk factors for gestational diabetes, another study suggested that screening only women aged ≥24 years would yield a cost per case diagnosed that is approximately 50% less than that of universal screening. In a population-based study[20] of 125 cases of gestational diabetes mellitus among 6214 pregnant women, sensitivity went from 65% to 85% when the age cutoff was decreased from >30 years (the current ACOG screening recommendation) to >25 years, while the cost per case diagnosed increased by only 1%! Thus no advantage is gained from a maternal age threshold for screening of 30 years, and the threshold could be decreased to 25 years with no increase in cost.

Screening patients exclusively on the basis of age fails to consider other risk factors. For instance, an obese 25-year-old gravid patient with a family history of diabetes has a risk of gestational diabetes mellitus equivalent to that of a nonobese 34-year-old woman without a family history.[22] Furthermore, gestational diabetes mellitus of a severity that poses increased risk of perinatal morbidity and mortality is likely to be found among both young and older gravid patients.[22] Ethnicity also affects the incidence of gestational diabetes. For example Navajo Indian women, Mexican women, women of Indo-Chinese descent, Chinese women with high prepregnancy ponderal indices, Saudi Arabian women, and black and Mexican teenagers have increased rates of gestational diabetes mellitus.

The issues of frequency and timing of glucose testing during pregnancy are linked to the issues of reliability of the individual tests and metabolic changes that are dependent on gestational age. Existing data[22, 23] suggest that glucose intolerance increases as gestation advances. Women with elevated glucose levels at screening and normal glucose tolerance test results early in pregnancy are at increased risk for the development of gestational diabetes mellitus later in pregnancy when compared with patients who have initially normal screening values.[22] Sequential screening, glucose tolerance testing,[23] or both[22] increase the yield of gestational diabetes mellitus identifications.

Universal screening for gestational diabetes mellitus, without regard to maternal age, is the most appropriate protocol. This recommendation is based on two lines of reasoning. The first is that gestational diabetes mellitus should be diagnosed because of the potentially preventable morbidity and mortality associated with this problem. In addition, adding complexity to test administration and interpretation leads to patient and physician error and noncompliance.[24] In the population-based study previously described,[20] 22% of pregnant women were under the age of 25 and had no risk factors for gestational diabetes; thus they would not have been screened. If a protocol requires historic risk factor evaluation, a decision must be made for each patient. Each decision point increases the possibility of error and takes the physician's time to consider the risk(s) and to explain to each patient why she does nor does not need screening. It would be more efficient and less error prone to use universal screening, in which a clerk would schedule the test automatically at 24 to 28 weeks' gestation and would provide each patient with a written explanation.

As a result of our study information, we recommend screening all pregnant women for gestational diabetes mellitus at least once during pregnancy. Testing between 24 and 28 weeks' gestation is late enough to demonstrate glucose intolerance but early enough to allow appropriate interventions. Patients with gestational diabetes mellitus risk factors may benefit from earlier screening. Patients with initially elevated screens that are followed by normal glucose tolerance tests may benefit from repeat testing later in pregnancy.

Oral glucose tolerance testing methods

If a patient's 1-hour 50 gm glucose screening level shows abnormality, she should be tested with the definitive diagnostic test, a 100 gm 3-hour glucose tolerance test.[1, 19] The patient is instructed to consume at least 150 mg of carbohydrate daily for the 3 days before the oral glucose tolerance test. The patient who is to have a 3-hour oral glucose tolerance test should take nothing by mouth overnight for at least 8 to 10 hours before the test.[1, 25] On the morning of the test the patient may drink water but should not ingest caffeine or food or liquid containing calories. It is also best that the patient not smoke for 12 hours before the test. Ideally, the patient should rest for approximately 30 minutes before the test. During that time period she may read, listen to the radio, and/or converse, but she should not move around. A heparin lock may be placed to avoid repeated needle sticks.

After the fasting sample is drawn, the patient drinks 100 gm of a glucose solution. For consistency, the timing clock is started as the patient begins to drink. The drinking should be completed within 5 minutes.[25] Subsequent blood samples are taken 1, 2, and 3 hours after the patient has drunk the glucose solution. During that time the patient should not move around or smoke.

When the test has been completed, the patient may eat or drink to minimize rebound hypoglycemia.

The rigorousness of the preceding methods does not apply when the patient has a 1-hour 50 gm glucose screen. Then the patient need not fast, be prepared by purposeful rest or diet before the test or be purposely isolated from activity. If the patient is a smoker, it is preferable that she not smoke a cigarette within 2 hours before the test.

In summary, we recommend: (1) Universal screening of prenatal patients for gestational diabetes mellitus should be done at least once during pregnancy. All prenatal patients should be screened, regardless of age, ethnicity or the presence of other risk factors for diabetes. (2) A 1-hour plasma glucose level after a 50 gm oral glucose challenge should be used for screening. (3) A screening threshold level no higher than 140 mg/dl should be used. (4) A "positive" screen should be followed up with the diagnostic 3-hour oral glucose tolerance test.

We gratefully acknowledge the valuable assistance of Ms. Vickie Carreiro and Ms. Terry Esler in the preparation of this manuscipt.

Embryonic ultrasonographic measurements: Crown-rump length revisited

Steven R. Goldstein, MD
New York, New York

New endovaginal probes will result in many investigators reexamining the crown-rump length data first generated with static arm and abdominal real-time scanners. As new tables are produced, only through better understanding of the anatomy of early embryos can we realize what we are actually seeing and measuring (or at least attempting to measure). Furthermore, as we try to correlate early embryonic size with gestational age, we realize that the crown-rump measurement is not applicable in principle or in nomenclature when the embryo is <18 mm long. When first seen, the embryo is relatively straight; a measurement of its size is best described as "greatest length." As the embryo curves into a C-shaped, tadpolelike structure, the greatest measurement along the long axis is actually a neck-rump measurement. Further unfolding of the head and regression of the tail finally allow an accurate crown-rump measurement (at about 18 mm) as we have used it for almost two decades. Early embryonic stages and characteristics are reviewed and methods of measurement of early embryonic size are explained. (AM J OBSTET GYNECOL 1991;165:497-501.)

Key words: Crown-rump length, embryology, ultrasonography, endovaginal ultrasonography, early embryonic size

In 1973 Robinson[1] introduced a new approach to the problem of assessing embryonic maturity during the first trimester of pregnancy by devising a technique for the ultrasonographic measurement of fetal crown-rump length. He provided a step-by-step description of how to take measurements with the static arm scanners that were the standard of the day.[2] Although the regression curve[3] is usually reproduced back to a menstrual age of 6 weeks 2 days (with a predicted crown-rump length of 6.7 mm), Robinson states that "when the crown-rump length is below 12 mm the technique described is not entirely applicable as the fetal length is at this time only marginally greater than its breadth."[1] This limitation of the technique was experienced by other authors performing studies with static arm scanners. The smallest mean crown-rump length reported by Drumm et al.[4] was 10.8 mm.

The widespread use of real-time ultrasonographic equipment made it technically easier to take such measurements. More investigators examined this area, but

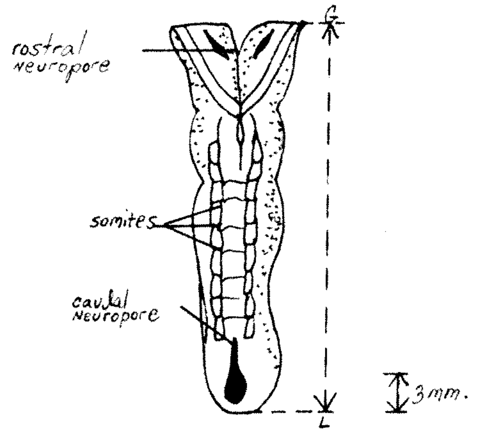

Fig. 2. This 3 mm embryonic structure clearly shows rostral and caudal neuropores. Embryo is fairly straight; measurement of its size is actually its greatest length *(G—L)*.

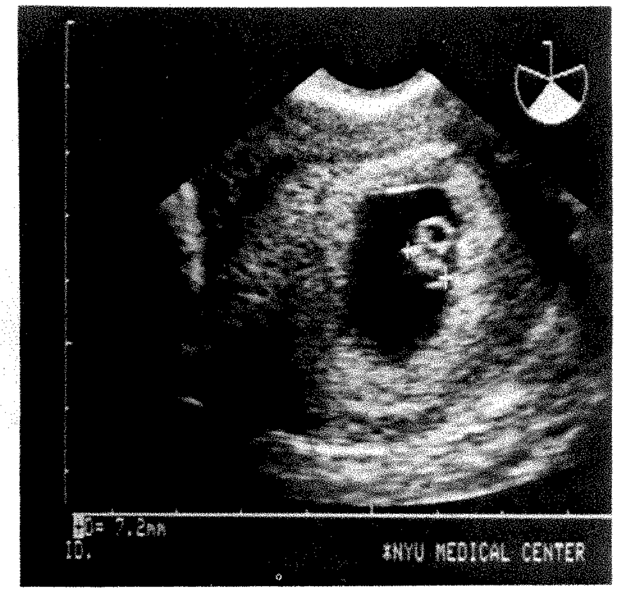

Fig. 3. Embryonic structure measuring 7.2 mm 50 days after mother's last menstrual period is well visualized in this gestational sac. Note again embryo adjacent to yolk sac.

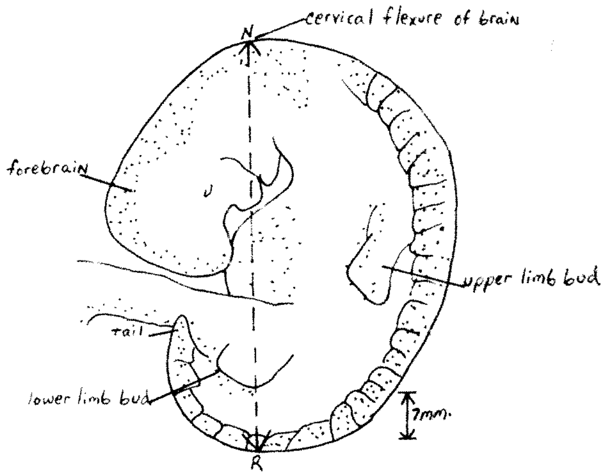

Fig. 4. Note C-shape assumed by this embryo of corresponding gestational age to embryo shown in Fig. 3. Forebrain has developed from rostral neuropore. Tail has developed caudally. Upper and lower limb buds are visible. Greatest measurement of embryonic size along long axis is 7 mm and represents neck-rump *(N—R)* measurement.

their findings were relatively similar.[5-7] A subsequent study of ovulation-timed pregnancies suggested that previous dating curves had underestimated gestational age.[8] Although the actual data points were not supplied, the graph and charts generated began with a crown-rump length of 10 mm.

The advent of new endovaginal probes provides such a degree of magnification as to be a form of "ultrasonomicroscopy."[9] It is as if we were doing ultrasonographic examinations through a low-powered microscope, imaging structures that we would not be able to see with the naked eye if those structures were held at arm's length. This new technology initially generated great interest in early pregnancy detection.[10] Now attention is turned to crown-rump length. Because we are able to image embryonic structures as soon as they appear distinct from the yolk sac, we must reevaluate the anatomy of what we are seeing and measuring ultrasonographically.

Historical background

Interest in establishing standard measurements for embryos dates back at least to the work by Mall[11] first published in 1918. He noted that the "main measurements employed were sitting-height and standing-height; these are known respectively as crown-rump and crown-heel."[11] Further, he noted that "it is well known that embryologists are given to using the crown-rump measurement for smaller specimens, while anthropologists and obstetricians generally use the crown-heel measurement for larger specimens."[11] The embryo's developmental stages, characteristics, and sizes were studied by embryologists.[12, 13] Early investigators of ultrasonographic measurements of crown-rump length[1, 4] made frequent reference to the embryologic staging and development of early embryos, even explaining why some of their data differed.

Embryologic stages

The distinction between embryo (from the Greek, meaning *metamorphosis*) and fetus (from the Latin, meaning *offspring*) is somewhat arbitrary. By 9 days after conception the embryonic complex, consisting of the primary yolk sac, embryonic disk, and amniotic cavity, is present.[14] Imaging the embryonic complex at this

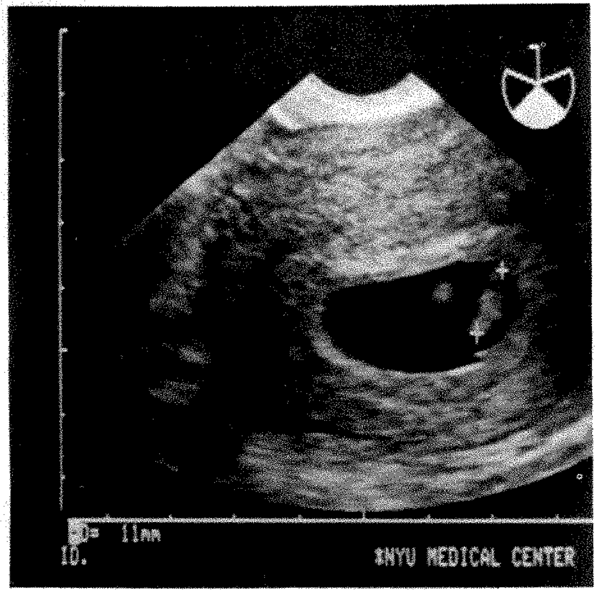

Fig. 5. Embryo measuring 11 mm at 55 days after mother's last menstrual period. See Fig. 6.

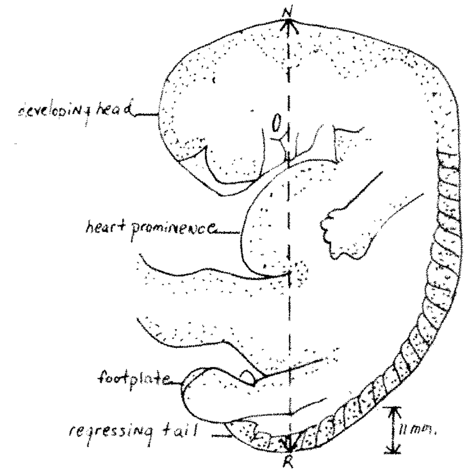

Fig. 6. Further development of head and its extension. Tail is regressing. Measurement along longest axis is from rump to cervical flexure (neck).

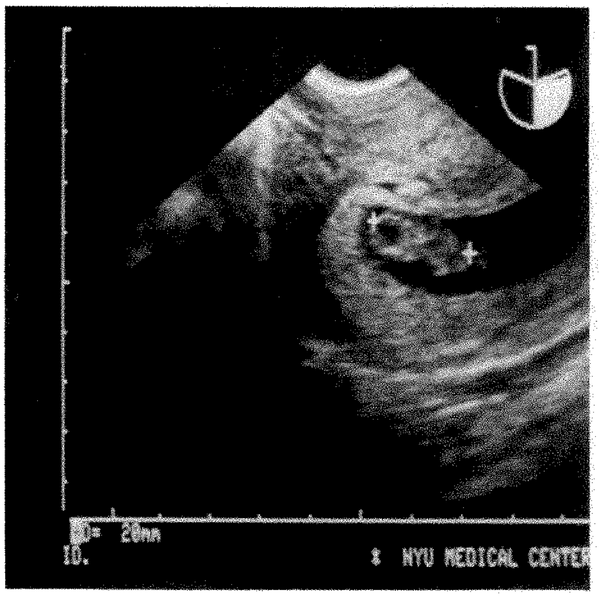

Fig. 7. Vaginal sonogram of embryo at 62 days after mother's last menstrual period. Crown-rump length is 20 mm. Sonolucent portion within head is developing rhombencephalon.

stage, however, is well beyond the capability of even the "sonomicroscopy" of our current vaginal probes. As gestation progresses, the first structure imaged within the gestational sac by ultrasonography is the yolk sac. The embryo and its cardiac activity are present, but they are still too small to be imaged (although with M-mode echocardiography a cardiac signal can occasionally be detected adjacent to the yolk sac).[15] Further embryonic growth is first noticed ultrasonographically as a thickening along the yolk sac. The following abbreviated description of embryonic stages and their appearance is meant to enhance understanding of the anatomy so that we realize what we are measuring (or at least striving to measure) ultrasonographically. The nomenclature needs to be revised: Crown-rump length is a convenient term, but when the embryo is <18 mm we are not really measuring crown-rump length.

Until the embryo reaches 3 to 4 mm in length it is straight (Figs. 1 and 2); instead of measuring crown-rump length, we are actually measuring greatest length.[16] The neural tube has formed opposite the somites. Rostral and caudal neuropores occupy the two distal portions. As the embryo grows, it curves until it is almost C-shaped (Figs. 3 and 4). The rostral neuropore closes, develops into the forebrain prominence, and becomes the head. The caudal neuropore elongates into a tail. The primitive heart still has great prominence. The greatest length along the longest axis begins to give way to a neck-rump measurement. This is the result of the extreme flexion of the developing head. With further development the tail regresses, the limb buds develop into hands and feet, the head begins to extend, and the heart remains prominent. The neck-rump length is now about 11 mm (Figs. 5 and 6). It is not until the greatest long-axis measurement reaches 18 to 22 mm that we approach the true crown-rump length measurement as we have previously understood it. The further unfolding of the head, the final regression of the tail, the development of the limbs and eyes, and the regression of the heart prominence allow what was previously a tadpolelike form to now be recognizable as an offspring (fetus) (Figs. 7 and 8).

When the crown-rump length reaches 35 mm (Figs.

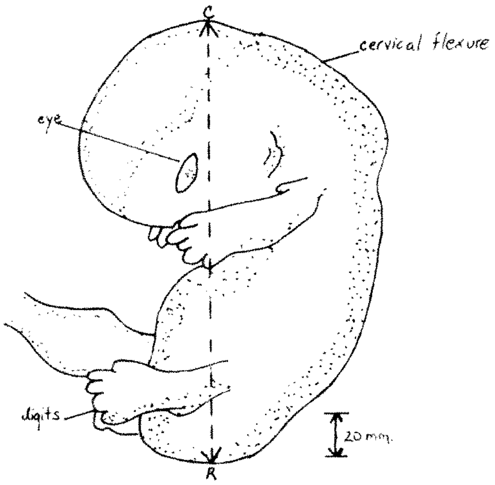

Fig. 8. Further extension and development of head and further regression of tail allow longest length of this embryo to be measured from crown to rump *(C—R)*. Note location of cervical flexure at this stage relative to its location in Figs. 6 and 4.

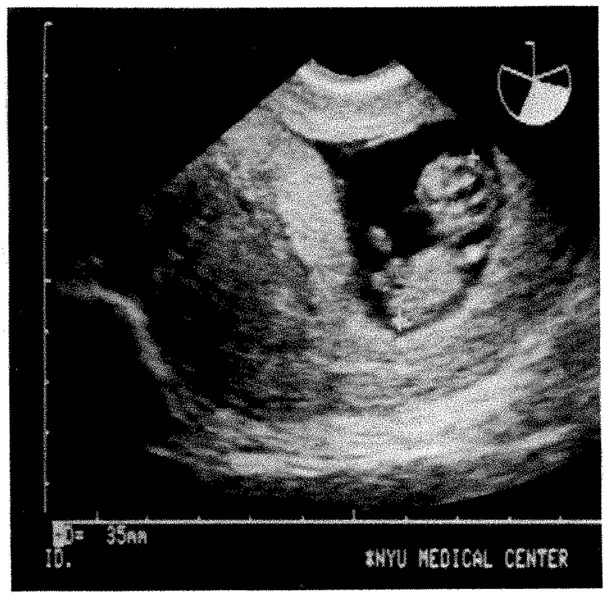

Fig. 9. Vaginal sonogram of a fetus at 72 days after mother's last menstrual period. Crown-rump length is 3.5 cm. Head, trunk, and limbs are readily recognizable.

9 and 10), even the most unsophisticated observers (the patient and her husband) can recognize the "baby," and the ultrasonographer is confident that the landmarks necessary for an accurate measurement are easily identifiable. This will remain true until the continued flexion of the fetus and the increasing ease of taking early biparietal diameter measurements cause the parameter of choice to switch from measurement along the long axis of the sitting embryo to measurement of the biparietal diameter.

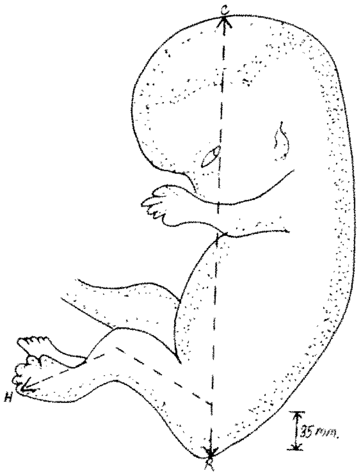

Fig. 10. This drawing corresponds to sonogram seen in Fig. 9. Crown-rump length is 35 mm. Distance from crown to heel *(C—H)* would actually represent standing height of fetus, as opposed to sitting height (crown-rump length).

Implications for crown-rump length charts to come

Experienced ultrasonographers have long realized that "one should use the average crown-rump length measurement from three satisfactory images."[17] This will not be difficult to do with confidence as the embryo enlarges (Figs. 8 and 10). However, even with the best of efforts, the measurements in very small embryos may be somewhat tangential and may not truly represent the greatest length, causing gestational age to be inaccurately estimated. This problem is similar to the problems initially encountered in measuring femur length. If great care to find appropriate landmarks is not taken, a slightly tangential view will show a deceptively short length. As new studies of early embryonic size are done, tangential views of very small embryos when compared with menstrual data (no matter how reliable the dates) will give a deceptively small *mean* embryonic size for a given menstrual age. Therefore maximum image magnification and the anatomic landmarks outlined should be used. When early embryonic size exceeds 18 mm and becomes a true crown-rump length (no longer a greatest length or neck-rump length), the likelihood of deceptively low measurements decreases.

Implications for crown-rump length charts currently in use

Investigators[4, 17, 18] have concluded that the original crown-rump length data by Robinson[1] remain the most reliable. The smallest crown-rump length image published from his work is 12 mm.[2] It is assumed that this represents the best of his available early images. None of the early crown-rump length observers mention the yolk sac; it was not yet ultrasonographically noticeable. It is conceivable that some of the very small crown-rump length measurements included a portion of yolk sac. Robinson himself was concerned about reliability of measurements <12 mm.

Measurements of embryonic size that truly represent crown-rump length (>18 mm) will still prove to be reliable even though the measurements originated in the static arm era. I believe that new and more sophisticated equipment and enhanced understanding of embryologic anatomy will enable us to construct dating charts of early embryonic size, taking the greatest measurement on the long axis. Because this goes from greatest length to neck-rump length and finally a true crown-rump length, it may be preferable to only use a generic term such as early embryonic size when describing embryonic length <18 mm.

Ovarian cancer screening: Potential effect on mortality

Carolyn Westhoff, MD, MSc,[a] and Mary Colleen Randall, MSc[b]
New York, New York

Serum tumor markers and ultrasonography are being investigated as possible ovarian cancer screening tests. Data from the United States on ovarian cancer incidence and survival were used to estimate the potential benefit on ovarian cancer mortality from screening tests of various sensitivities. A test with 80% sensitivity could reduce ovarian cancer mortality by 50% if all screening-detected cases were to experience current stage I survival rates; the benefit would be greatest among women aged 45 or older. For each cancer detected there would be at least 50 false-positive screening tests unless test specificity is >98%. If our most optimistic assumptions about screening could be met, then universal periodic screening of women aged 45 to 74 would result in about 5000 additional 5-year survivors of ovarian cancer annually. Uptake of existing screening tests is far less than universal; thus we would expect the impact of any ovarian cancer screening program to fall short of these projections. (Am J Obstet Gynecol 1991;165:502-5.)

Key words: Ovarian cancer screening, ovarian cancer mortality

Screening for early detection of certain cancers in women has proved effective. The Papanicolaou smear is credited with reducing mortality rates from cervical cancers,[1] and mammography is leading to earlier detection of breast cancer, although the use of mammography has yet to translate into a decrease in mortality in the general population.[2,3] Gynecologists are now considering whether deaths that result from ovarian cancer also might be prevented by the identification of and use of a screening test for this disease. Many investigators in the United States and Europe are evaluating the use of modalities such as urine or serum tumor markers and ultrasonographic imaging for the early detection of ovarian cancer.[4-8] Public belief in the value of screening is leading to a demand for these tests before their value has been demonstrated.

This article examines the reduction in ovarian cancer mortality that might be achieved if we can develop a screening test for the detection of this disease during its preclinical phase. We also consider how many screening tests would have to be performed to gain each additional survivor, how many false-positive tests would occur, and how large a study would be required to evaluate a mortality reduction that resulted from screening.

Methods

Calculating the effect of screening on ovarian cancer mortality in the United States required estimates of the number of cases and deaths from ovarian cancer by age and stage at diagnosis. These were extrapolated from data collected from 1973 to 1986 by means of a public-use data tape of the Surveillance, Epidemiology and End Results (SEER) program of the National Cancer Institute. Age-specific, stage-specific 5-year ovarian cancer survival rates are based on the experience of women with follow-up in SEER registries from 1973 to 1980.[9] Additional data regarding survival rates for stage IA and IB disease were taken from a randomized trial of treatment.[10]

To estimate the effect of a screening test on survival, we assumed that women whose cancers were detected by screening would experience survival rates equal to or better than those currently experienced by women in the same age group in whom diagnosis was made at stage I. We varied the sensitivity of our hypothetical screening test from 70% to 90% because this is comparable to the best sensitivities reported for Papanicolaou smears[11] and mammography.[12] Sensitivity is the percentage of test results that are positive among women with the disease. We assumed that cases detected and cases missed by screening have the same age and stage distribution and the same mortality in the absence of screening.

The main outcome in this analysis is the number of

ALL	82	60	17	26	38

additional 5-year survivors in the hypothetical screened population. In our model lead time does not contribute to the additional survival. Calculation of the number of screening tests required for each additional 5-year survivor assumes that tests are performed on an annual schedule; another periodic schedule may prove to be more appropriate. The female population at risk was estimated by taking 1986 United States female population figures[13] and subtracting the estimated proportion of women who underwent bilateral oophorectomy in each age group.[14]

The number of false-positive screening tests that would occur was calculated for specificities of 90% and better. Specificity is the percentage of test results that are negative among women without the disease. The number of true-positive test results that would occur in the same population was calculated for test sensitivities of 70%, 80%, and 90%. The positive predictive value of the test was calculated for each combination of sensitivity and specificity. The positive predictive value is the percentage of all positive test results that are true positive.

In a randomized controlled trial of screening the 5-year survival rate for screened cases would be a result of both decreased mortality and lead time; therefore our calculations to estimate the sample size needed for a randomized controlled trial considered total cohort mortality and not case survival rates. We present the results for a trial that would be able to detect a 50% reduction in mortality that resulted from screening with a one-sided significance level of 0.05 and power of 0.80.[15] We chose a one-sided significance level because we had no suspicion that there would be an increase in ovarian cancer mortality as a result of screening. Calculations throughout were performed for 5-year age groups wherever sufficiently detailed data were available, but for brevity results are presented in less detail.

Results

About 20,000 cases of ovarian cancer occur annually in the United States; these cases are distributed by age and stage as shown in Table I. Sixty-five percent of these cases are diagnosed at stage III or worse, and 85% occur in women older than 45 years. Of these 20,000 cases there will be about 7600 5-year survivors. The percentage of 5-year survivors by age and stage is shown in Table II. Young women have better survival both because they tend to have the diagnosis made at earlier stages and because they experience better stage-specific survival rates than do older women. The effect of universal use of a screening test with 80% sensitivity would be to increase the number of 5-year survivors (at all ages) from 7600 to 14,400. Nearly all of this benefit would occur among women with screening and diagnosis after age 45 (Fig. 1); from age 45 to age 74 the number of 5-year survivors would increase from 4700 to 9350.

Fig. 2 demonstrates the number of screening tests that would need to be performed in each 5-year age group to gain one additional survivor per year. Because cases are rare and survival is relatively good below age 45, ≥40,000 screening tests would be required to yield a single additional survivor at such young ages. From age 45 to 74 there are about 27 million women with at least one ovary who would be candidates for screening.

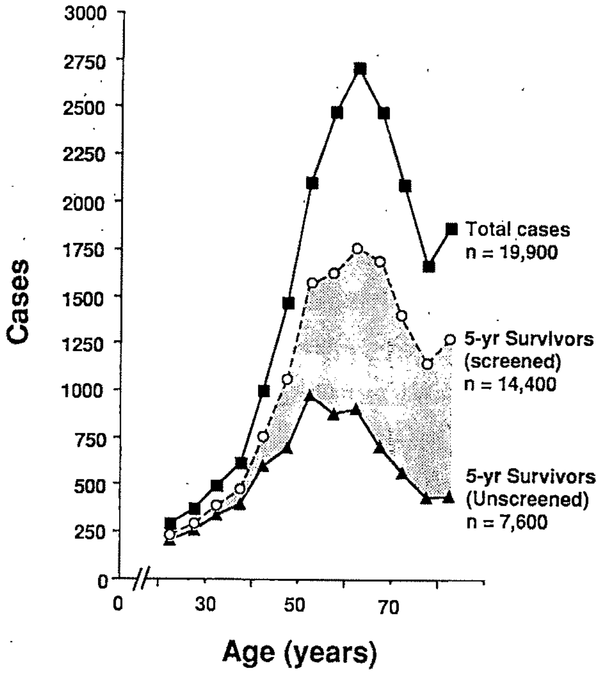

Fig. 1. Ovarian cancer cases and 5-year survivors by age. Unscreened and screened population. Screening test with universal uptake and 80% sensitivity.

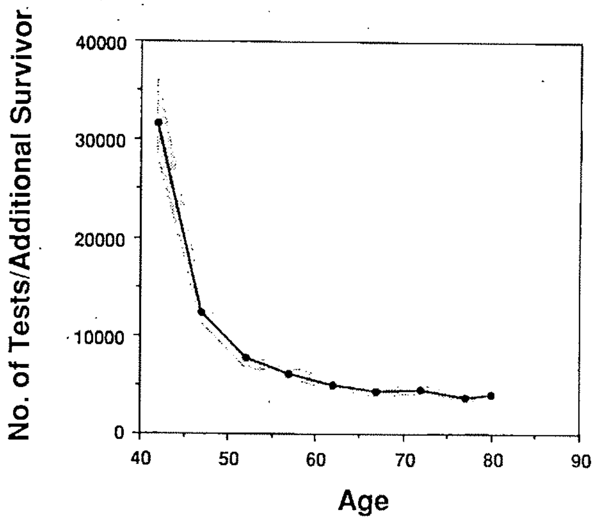

Fig. 2. Number of screening tests required to gain one additional 5-year survivor (by age). *Solid line* indicates test with 80% sensitivity; *surrounding band* includes all sensitivities from 70% *(upper bound)* to 90% *(lower bound)*.

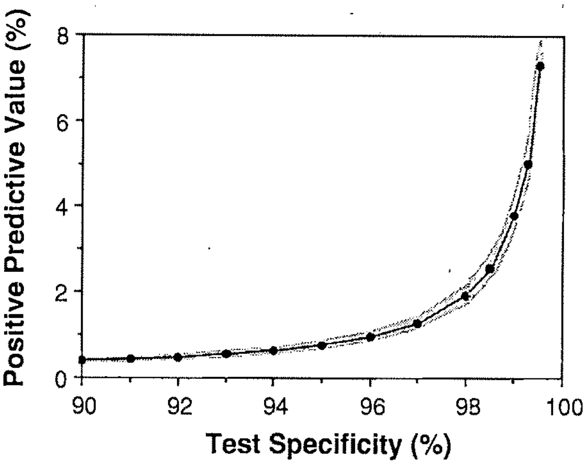

Fig. 3. Positive predictive value of screening according to test performance. *Solid line* indicates test with 80% sensitivity; *surrounding band* includes all sensitivities from 70% *(lower bound)* to 90% *(upper bound)*.

Among these women approximately 6000 tests would be required to gain an additional survivor if the test were 80% sensitive. If it were 70% sensitive, then 6850 tests would be required to gain an additional survivor. If the sensitivity of this hypothetical test increased to 90%, then about 5300 tests would be required to gain an additional survivor in this age group.

The most optimistic data on stage IA and IB disease show 5-year survival rates that approach 95%.[10] If such survival rates applied to screening detected cases (with an assumed 80% sensitivity) from ages 45 to 74, then there would be about 11,100 5-year survivors in this age group instead of the 4700 survivors expected in the unscreened population. This equals one additional survivor for every 4400 women screened.

Fig. 3 demonstrates the improvement in positive predictive value that would occur among women aged 45 to 74 as test specificity increases. For specificities of ≤98% there would be at most one woman with ovarian cancer among 50 women with a positive screening test result. In women younger than 45 years the positive predictive values are much lower than those shown in the figure because the disease is so rare.

If the hypothetical screening test has a sensitivity of 80% and if all screening-detected cases have current stage I mortality rates, then screened women aged 45 to 74 would experience about a 50% reduction in mortality from the disease. Even such a large effect of screening would be difficult to detect in a clinical study because of the rarity of this disease. The unscreened women participating in a randomized clinical trial of annual screening would have to experience at least 80 deaths from ovarian cancer during follow-up, while an equal number of screened women would have to experience fewer than 40 deaths for the improvement in the screened group to be statistically significant. A randomized trial of annual screening that includes and monitors about 100,000 women aged 45 to 74 (50,000 screened and 50,000 unscreened) for at least 6 years would be required to have the statistical power to detect this estimated 50% reduction in mortality.

Comment

Our estimates of the maximum survival benefit that might be obtained by screening for ovarian cancer were based on cancer incidence and survival data from

SEER, which covers about 10% of the country. The population covered by SEER is unlikely to differ in any important way from the country as a whole. Our calculation of the population at risk of ovarian cancer (women with ovaries) was based on survey data from upstate New York,[14] which may not be representative of the rest of the country; national data on the prevalence of oophorectomy by age would be valuable for these (and other) calculations. We believe that the number of additional 5-year survivors is a simplistic but reasonable surrogate for the number of lives that might be saved by screening, because most of the current mortality from ovarian cancer occurs within 3 years of diagnosis.[9]

In addition to reduced mortality, possible benefits of screening not considered here might include an increase in the quality of life for women with disease or a decrease in the costs of treatment. The only way to reliably measure most benefits would be by means of a randomized trial. Such a trial could also identify and quantify the adverse effects of screening, such as the number of and consequences of false-positive screening test results and the costs of screening. Randomized controlled trials that enroll fewer than 100,000 women or that monitor these women for <6 years would be unlikely to detect even a 50% reduction in mortality. Similarly, trials that evaluate a screening test that is <80% sensitive or that include women younger than 45 years will not be able to demonstrate this benefit of screening, even if such benefit exists. Ongoing observational studies[5-7] that include a few thousand women will yield important information about the screening tests evaluated, but such small studies lack the statistical power to detect an effect of screening on mortality.

We estimate that the maximum possible benefit of screening would be to save approximately 4000 to 6000 lives per year, if all 27 million American women aged 45 to 74 with ovaries are screened periodically. Screening of younger women would have a much lower yield. The maximum benefit is unlikely to be achieved because experience with Papanicolaou smears and mammography indicates that only a minority of women at risk take advantage of screening.[3, 16] In addition, our assumption that screening-detected cases would experience stage I mortality rates may be far too optimistic.[17] Thus the number of lives to be saved annually in the United States from an ovarian cancer screening program would probably be substantially fewer than 4000 to 6000.

The development and evaluation of an effective screening test for ovarian cancer will require additional research; as a result of the limited numeric benefit of screening estimated here, the priorities in such research should be the identification of subgroups of women who are at extremely high risk for this disease and a search for tests that are highly specific, as well as the further evaluation of very inexpensive tests. It is currently inappropriate to offer tests such as CA 125 and ultrasonography for the purposes of screening asymptomatic women for ovarian cancer, because no benefits of these approaches have been demonstrated. Meanwhile, it seems reasonable to advise our younger patients who are worried about ovarian cancer that they can reduce their risk of this disease by approximately 50% if they choose to use oral contraceptives[18]; this route of prevention is available to nearly all young women and could make as great a contribution to the prevention of ovarian cancer deaths as would the best possible screening program, according to our estimates.

Prenatal behavioral risk screening by computer in a health maintenance organization–based prenatal care clinic

Sandra C. Lapham, MD, MPH,[a] Michael K. Kring, BSCS,[b] and Betty Skipper, PhD[c]
Albuquerque, New Mexico

Cigarette smoking, alcohol and drug abuse, and stressful life events are significant contributors to prematurity and low birth weight in the United States. Identification and treatment of pregnant women with these risk factors require obtaining complete and accurate psychosocial histories. The purpose of this study was to determine whether a computer interview developed by our staff is appropriate for assessing behavioral risk factors for adverse pregnancy outcomes and for educating pregnant women about healthy behaviors during pregnancy. This computer interview asks about pregnant patients' perceived life stressors, diet, use of cigarettes and alcohol, and abuse of drugs. The study population consisted of 201 medically insured Hispanic and non-Hispanic white women attending a health maintenance organization–based prenatal clinic. Almost all subjects rated the computer interview favorably. Medical record reviews were conducted to compare participants' reports of cigarette, alcohol, and drug use obtained from paper-and-pencil interviews with behaviors reported during the computer interview. Although self-reported rates of smoking did not differ between the two interview techniques, a much higher percentage of women reported alcohol and drug use during the computer interview. Study participants scored significantly higher on a test measuring knowledge of the effects of stress, diet, and substances of abuse on pregnancy than did a control group. Results demonstrated the potential value of computer-interactive software programs for assessing high-risk behaviors among pregnant women in this population and educating them about healthy behaviors during pregnancy. (AM J OBSTET GYNECOL 1991;165:506-14.)

Key words: Computer, screening, prenatal education, substance abuse

Smoking and drinking alcohol are prevalent behaviors among the United States population.[1] Although public awareness of the risks of cigarette smoking and alcohol and drug use during pregnancy has increased,[2] many women report that these issues are not discussed as part of their prenatal care.[3-5] Medical personnel also have difficulty obtaining accurate information from patients about alcohol use and substance abuse. An investigation by Morrow-Tlucak et al.[6] demonstrated underreporting of alcohol use during pregnancy by a significant proportion of women. Another study by Zuckerman et al.[7] revealed that of 202 pregnant women whose urine assays were positive for marijuana and 114 women whose urine assays were positive for cocaine, 16% and 24%, respectively, had denied having used these drugs.

Patient-interactive computer interviews have demonstrated value in obtaining medical histories and educating persons about behavior-related health problems.[8-10] Although there are no published studies investigating the efficacy of computer-based interviews when used in pregnant populations, this technology is easily adapted for screening and health education in a prenatal care clinic setting.

We have developed a personal computer–based software program to identify high-risk behaviors and to educate patients about healthy behaviors during pregnancy. This program: (1) assesses the behavioral risks of pregnant women, (2) provides educational information to patients in the form of personalized feedback, provided both on the video screen and on computer-generated printouts, (3) offers a resource directory of specialized health care services available to assist high-risk patients, and (4) collects anonymous prevalence data regarding reported behavioral risk factors in the population under study. Topics addressed during the interview include cigarette smoking, alcohol and drug use; optimal eating habits during pregnancy; and the importance of stress management.

We wish to report the results of a study conducted among medically insured Hispanic and non-Hispanic white women attending a health maintenance organization–based prenatal clinic. The objectives of the study were (1) to determine whether this patient-

interactive computer interview is well accepted in this population, (2) to determine the educational value of the program, (3) to determine the validity of self-reported information on cigarette and drug use provided during the computer interview, and (4) to compare reports of substance abuse provided during the confidential computer interview with that currently being obtained through patient self-reports of high risk behaviors on a written questionnaire.

Material and methods

Description of the computer program. The Pregnancy Information Program has two important features: a flexible format, which allows programming and text changes to address specific needs of differing patient populations, and strict confidentiality protection. It is divided into eight sections: general information, stress, nutrition, cigarette smoking, alcohol use, use of other drugs of abuse, program evaluation, and printouts. The program was developed with the Knowledge Man data base management system (Micro Data Base Systems, Lafayette, Ind.) and is designed for use by persons with no computer experience or typing skills. The program text consists of multiple choice questions, written at a sixth- or seventh-grade reading level, that can be answered by typing in a number. A fiberglass overlay covers the keyboard, exposing only the number keys and the return key. The subjects can answer all questions by entering one of 10 numbers and pressing the return key. The subjects' answers are checked by the Pregnancy Information Program to determine if they are in the correct range, and they are verified by the subject. Feedback is provided by the software's simple graphics in a range of screen colors. The program collects information about the patient's eating habits, life-style practices, and life situations; explains known health effects of the behaviors under investigation; provides individualized visual and printed feedback—immediate information about how the patient's behaviors may be affecting herself and her fetus; asks the participant to rate the computer program; and generates a participant and a provider printout summarizing the assessment.

The format of this interview is similar to that of the Lifestyle Assessment for general adult medical patients developed by Allen and Skinner[11] and has features similar to health risk appraisals used in community health promotion programs. However, no risk estimates are provided in the Pregnancy Information Program. Since patients may equate risk with cause and may not understand the concept of risk, the program does not use the term *risk*. Feedback is given in simple terms, such as "studies have shown that smoking can harm the baby" or "your baby could be healthier if you stop drinking alcoholic drinks while pregnant." When statements include the concept of risk, the wording is as follows: "this may increase the chance that" or "you are more likely to have a healthy baby." The feedback information is not a fear message and does not exaggerate the health effects of the behaviors discussed.

Efforts were made, when possible, to use preexisting, validated questions for specific sections of the program. A description of each section follows:

Section 1: Demographic information. This section requests the following: name, date of birth, weeks' gestation, number of previous pregnancies, number of children, years of education, ethnicity and race, number of children and adults in the household, marital status, and income.

Section 2: Stress (psychosocial risk). The computer program includes questions designed to identify women experiencing symptoms of psychologic distress. Specific questions ask whether the patient is the victim of domestic violence or is living with an alcohol or drug abuser. Questions also are asked about the patient's own perception of her level of stress, anxiety, and depression; whether she has support from family members or friends; her usual methods for dealing with stress; and whether the pregnancy was wanted.

Section 3: Nutrition. A complete assessment of the adequacy of dietary intake is not possible within the limitations of a brief computer program. The Pregnancy Information Program simply provides examples of foods belonging to each of the four basic food groups, defines a serving size, and asks the patient about her usual daily intakes of servings from each group. Feedback is consistent with current guidelines for optimal dietary intakes provided by the Women and Infant Care Guidelines.[12] Information provided to participants includes education about optimal weight gain during pregnancy and reinforcement that meals should be balanced according to the basic food groups.

Section 4: Cigarette smoking. Questions were designed to collect accurate information on this and other sensitive topics in a nonthreatening manner. Information gathered includes whether the participant smoked during previous pregnancies, number of cigarettes smoked before becoming pregnant, number of cigarettes currently smoked daily, previous attempts to quit, the participant's view of how smoking may affect her own health and the health of the fetus, and the smoking status of the baby's father. Some of the questions used (with permission) in this interview were developed by Roger Secker-Walker, MD, Professor of Medicine, University of Vermont, Burlington. Feedback and education stress the positive benefits of quitting smoking and effective methods to quit.[13] A special section written for smokers not only provides information about smoking during pregnancy but also attempts to dispel some of the myths about quitting smoking. The program then provides a short self-help method for quitting.

Section 5: Alcohol use. Patients were asked about the

frequency and quantity of their alcohol consumption before and during this pregnancy. Questions on alcohol use and corresponding feedback were derived (with permission) from the "Ten Questions Drinking History" used at the Boston City Hospital's Fetal Alcohol Education Program, Boston.[14]

Section 6: Use of drugs of abuse. Patients were asked specific questions about their present and prior use of marijuana, amphetamine-like drugs (including cocaine), opiates, barbiturates (and other "downers"), tranquilizers, hallucinogens, and inhalants. The assessment questions were developed by Drs. Allen and Skinner for their Lifestyle Assessment[11] and were modified and adapted for the Pregnancy Information Program.

Section 7: Computer program evaluation. The computer interview also queries whether the participant liked the program; learned anything new about each of the subjects covered; was honest; would have been more or less honest if interviewed in person or by a paper-and-pencil interview; would prefer a computer, face-to-face, or paper-and-pencil interview; and whether the program took too much time to complete. All questions are answered with a seven-point rating scale, with responses ranging from strongly agree, agree, somewhat agree, don't know, etc., to strongly disagree.

Section 8: Printouts. The first computer printout is for the patient's use. It presents a summary of her individualized feedback and, for those who have identified a behavioral risk factor, provides educational material and a menu of options for obtaining information or assistance in changing unhealthy behaviors or situations. Included in this menu are options for specialized care available to the patient at the care-giving institution, lists of community resources, and lists of self-help literature. This menu can easily be custom programmed to meet the specific needs of individual offices, clinics, or institutions. The second printout is a one-page provider summary (Fig. 1). The program encourages women to share this printout with their providers.

Procedures. All patients who were within the first 20 weeks of pregnancy were eligible to participate. The study was conducted at the Lovelace Medical Center, Albuquerque, from January through December 1988. At the time of the study about 30 to 40 patients per week underwent their first prenatal examinations at the prenatal clinic. The study protocol was approved by the

Lovelace Medical Center's Institutional Review Board.

Participants were recruited by a trained project associate who explained the study to prospective subjects and asked them to provide informed consent. All participants were told that the information collected during the interview would remain strictly confidential and would not be given by the investigators to their health care providers. All women who agreed to participate received the computer program. On completion of the Pregnancy Information Program, the women were given both computer printouts. Participants had the option of giving the provider summary to their physicians. Attempts were made to enroll all eligible patients. Those who refused were asked to complete a postcard survey anonymously, containing such information as age, ethnicity, marital status, number of pregnancies, education level, and employment status, to assess possible biases introduced by patient self-selection into the study.

Urine specimens were obtained from all study subjects at the time of the computer interview, to validate their reports of nonuse of cigarettes and use or nonuse of drugs of abuse. All participants received the Wide Range Reading Achievement Test (Jastak Associates, Inc., Wilmington, Del.) before completing the computer program. Most subjects received the program before their first prenatal visit. All participants participated in the standard program for prenatal care and health education offered by Lovelace Medical Center.

Smoking status was determined by measuring cotinine levels in urine. Cotinine is a direct metabolite of nicotine and, unlike nicotine, has a relatively long half-life.[15] Cotinine can be quantified by a radioimmunoassay technique developed by Langone et al.[16] and has been shown to be a valid indicator of tobacco smoke exposure.[17] Furthermore, cotinine levels in urine and saliva have been shown to correlate well with those in plasma.[17] Urine cotinine and creatinine ratio analyses were performed at the Clinical Research Center Laboratory, University of New Mexico School of Medicine, Albuquerque. Urine cotinine measurements >49.6 ng/ml were considered presumptive evidence of active smoking.[18]

Urine samples were screened by radioimmunoassay at the University of New Mexico Toxicology Laboratory for the following classifications of drugs of abuse: opiates, cocaine and other stimulants, tetrahydrocannabinoids, benzodiazepines, and barbiturates. Positive results were verfiied at the same laboratory by gas chromatography–mass spectrometry.

To evaluate the educational component of the Pregnancy Information Program, a 33-item test was designed by Lovelace research staff to evaluate participants' knowledge of the four basic food groups, the definition of stress, the effects of cigarette smoking, and the effects of use of drugs of abuse during pregnancy.* This test was validated among patients at the Lovelace Medical Center clinic; then it was administered to 169 subjects who had received the Pregnancy Information Program from 12 to 20 weeks earlier in their pregnancies and, finally, to a comparison group consisting of 66 patients in the third trimester of pregnancy who were receiving prenatal care at Lovelace Medical Center and who had not been offered the computer program.

After each participant gave birth, a trained abstractor, who did not know the purpose of the study and had no information regarding the responses given by participants to the computer interview, reviewed each of the medical records. Chart reviews were conducted for 196 (97%) of the 201 subjects. Five medical records were missing or unavailable, and five additional records contained incomplete information. Information abstracted from the medical record included participant responses to a written questionnaire that queried the patient's use of cigarettes, alcohol, and drugs of abuse. This questionnaire was administered to participants in a group setting as part of a prenatal education class. Women completed this questionnaire 1 day to 4 weeks before they received the computer interview.

Data from the computer-assisted program were stored on the personal computer's hard drive and on floppy diskettes. Data were then transmitted by floppy diskette to a minicomputer for storage and subsequent data analysis. Pregnancy Information Program information, laboratory results, results of the reading tests, and information collected from the medical records were entered directly into a computer file. All data collected for each subject were expanded into single sequential records. Records were processed and analyzed statistically by a series of SAS (Statistical Analysis Systems Institute, Raleigh, N.C.) programs.

Results

Participation rate and characteristics of participants. Of the 229 eligible women who were asked to participate in the study, 201 (88%) agreed to participate. One woman agreed to take the program but refused to provide a urine specimen. The most commonly used reason for nonparticipation among the 28 nonparticipants was "not enough time" (54%), followed by "not interested in the study" (25%). One woman expressed a dislike of computers, and one woman felt her reading skills were too poor.

Characteristics of participants and nonparticipants were similar. The study population was almost equally divided between Hispanic (48%) and non-Hispanic (49%) white women. Ages of participants ranged from

17 to 42, with a mean of 28 years. The mean number of years of school completed was 13, and all but one of the participants read at a minimum eighth grade reading level. Approximately 74% were married; the current pregnancy was the subject's first for 26% of the participants. The majority of the subjects were employed full-time (59%) or part-time (13%). Almost all of the participants either were members of the Lovelace-affiliated health maintenance organization (81%) or had other health insurance (16%).

Participant ratings of the computer interview. Almost all (94%) of the participants liked the computer interview (Table I). Only 6% of the patients agreed with a statement indicating they would prefer a written questionnaire to the computer interview (Table I). Computer interviews conducted among the 201 subjects in the Lovelace population averaged 30 minutes to complete; 11% of the participants thought it took too much time to complete.

Health education value of the computer program. Most of the study participants (76%) reported during the evaluation section of the computer interview that they "somewhat agreed, agreed, or strongly agreed" with a statement indicating they learned new information about at least one of the topics included in the interview. The subject about which the highest percentage of women reported learning new information was nutrition (77%) (Table. I). Using general linear model regression, younger age, fewer years of education, lower income, and Hispanic ethnic group each were found to be positively associated with responses indicating the participants learned new information about the risk factors discussed in the Pregnancy Information Program.

The mean score on the test measuring knowledge of behavioral risk factors was 83% correct responses for study participants, compared with 79% for the controls ($p = 0.01$). Participants, however, were older and had higher income levels than controls, requiring use of a statistical model to further assess whether the relationship (between higher scores and having taken the computer program) would persist after controlling for the effects of these two factors. A general linear models procedure was used, in which age, exposure to the computer program, income, ethnicity, and years of education were independent variables, and score on the test was the dependent variable. The overall R^2 of the model was 0.40, and the p value for having taken the computer interview was 0.04, indicating a positive relationship between scores on the test and having received the computer interview.

Validity of the computer interview

Self-reported honesty. Ninety-three percent of the Lovelace participants agreed with the statement that they were "totally honest" during the computer interview; however, 5% disagreed with this statement and 2% responded "don't know" (Table I); 52% agreed with the statement that they were more honest to the computer than they would have been in a personal or paper-and-pencil interview. In response to the statement, "I will give my doctor the report of my life-style habits," 52 women (26%) reported "don't know" and 143 women (68%) agreed (Table I). More than 20% reported they would be less honest if their answers were given to their doctors and added to their medical charts.

With the answers provided during the evaluation section of the computer questionnaire, it was possible to determine factors that were associated with reported honesty and willingness to share information with the participants' providers. Statistical comparisons were drawn between participants' demographic characteristics and their self-reported behaviors, to further elucidate the relationship between reported risk factors, and statements about reported honesty and feelings about the confidentiality of the computer interview (Table I). With general linear model regression, current use of alcohol and drugs was found to be associated with a higher degree of agreement with the statement, "I would be less honest if my answers were given to my doctor and added to my medical chart" ($p = 0.001$ for drug users and $p = 0.014$ for alcohol users). Those who used drugs also were more likely to report higher levels of agreement with the statement, "I was more honest in this interview than I would be in a personal or paper-and-pencil interview" ($p = 0.004$), and to have lower levels of agreement with the statement, "I will give my doctor the report of my life-style habits" ($p = 0.0001$).

Urine testing. Of the 201 women enrolled in the study, 17% stated they were current smokers. A random sample of 71 urine specimens was analyzed for cotinine levels from among the 167 women who stated that they were currently nonsmokers. Results revealed that 7% of these women had urine cotinine levels indicative of active smoking (Table II).

Data regarding use of drugs of abuse (Table III) indicated that few of the participants used illicit drugs. Eleven women admitted to current marijuana use. One additional woman reported current use of cocaine. Of 67 women who did not report current drug use, and whose urine specimens were randomly selected and assayed for drugs of abuse, 2 (3%) were positive.

Table II. Urine cotinine concentrations among participants

Reported smoking status	*Elevated cotinine**	*Discordance*	*95% Confidence interval*
Never smoked ($n = 39$)	1	5/71 (7.0%)	2.3%–15.7%
Quit smoking ($n = 32$)	4		

*Urine cotinine level >49.6 ng/mg of creatinine.

Table III. Results of urine assays for drugs of abuse among participants

Reported drug use	*Positive test (substance)*	*Discordance*	*95% Confidence interval*
No ($n = 67$)	2*	2/67 (3.0%)	0.4%-10.4%
Yes ($n = 3$)	1*†; 2, Negative‡		

*Tetrahydrocannabinoids.

†Reported last use 7 days ago.

‡Reported last use of marijuana 7 days ago and >4 weeks ago. Both reported frequency of use as less than once per week.

Comparisons between reports to the computer and information in the medical record. Comparisons between behaviors reported by patients to the Pregnancy Information Program and patients' responses to a written questionnaire placed in the medical chart revealed that the computer interview obtained results similar to those of the written questionnaire for ascertaining smoking status (Fig. 2). However, a statistically higher percentage of subjects reported alcohol and drug use to the computer than they reported in the written questionnaire (Fig. 2). Of the 47 discrepancies noted between alcohol use recorded in the medical chart and behaviors reported in the computer interview, in all but five instances the discrepancy was accounted for by a negative patient report in the written questionnaire and a positive report of alcohol use in the computer interview. There was no reported use of substances of abuse in the medical record, compared with 11 reports of marijuana use during pregnancy and one report of cocaine use provided during the computer questionnaire.

Comment

The results of this study demonstrate that computer interviews can be a useful adjunct to prenatal care among well-educated, medically insured, white, Hispanic and non-Hispanic patients. The Pregnancy Information Program format was well received by study participants. Ninety-four percent of the women enrolled in the pilot study indicated that they liked the

Fig. 2. Comparisons between reports to computer and responses to written questionnaire.

computer interview, and almost 95% of the participants preferred the computer interview to a written questionnaire. Of the 201 women in the study, only about one in four (27%), "somewhat agreed" to "strongly agreed" with the statement that they would rather be interviewed by a person than by a computer. A potential problem reported in the literature—that some individuals are uncomfortable with or afraid of computer interviews[19]—was not a problem in this study. None of the participants was intimidated by the computer interview and only one of the nonparticipants indicated that her lack of interest in participating was due to a dislike of computers. The high participation rate in this study indicated a strong interest among women in this population to experience new health education approaches. Therefore the health maintenance organization setting may be one that is optimal for use of patient-interactive computer programs.

Results of this study also support the premise that computers can be useful for patient education. More than 75% of women who completed the Pregnancy Information Program reported agreement with the statement that they learned new information from the program. Scores on a test measuring knowledge of the risk factors discussed in the program were higher among study participants than among controls who were not offered the program. These results support the work of Paperny and Starn,[20] who have developed color graphics computer games that provide educational information for adolescents about unhealthy behaviors. In an evaluation of two of the programs, *Babygame* and *Romance*, users of the program became more aware of factors such as the cost of giving birth to and raising a child and they became more knowledgeable about the safety and efficacy of contraceptives.[20] The current prenatal program at Lovelace Medical Center contains a patient education component. Most of the women in the control group scored well on the test, indicating awareness of the possible consequences of high-risk behaviors during pregnancy. Therefore it was not possible to evaluate the impact of the computer-assisted program as a singular entity but rather as an adjunct to the specific program of prenatal care offered by the study institution. In spite of this and the relative simplicity of the Pregnancy Information Program, most of the women stated they learned new information. Many participants also indicated that the program would motivate them to make behavioral changes; 68% stated they would change their behavior after the computer interview. However, whether changes actually occurred must be determined in further studies.

The third objective of the study was to determine the validity of the Pregnancy Information Program in obtaining accurate behavioral risk information. Rates of participants' self-reported honesty and results of the urine assays conducted for this study support the conclusion that the information provided by participants was valid. The concordance rates—between self-reports of smoking and drug use and results of urine assays—were 93% and 97%, respectively. However, these screens will detect recent users only. Most of the urine assays for drugs of abuse are not sensitive enough to detect drugs taken >3 or 4 days before sampling. Exceptions include marijuana (detectable for as long as 30 days for a heavy marijuana user, 7 to 10 days for a moderate user, and 3 to 5 days for a light user), phenobarbital (detectable for 2 to 3 weeks), methaqualone (detectable for 2 weeks), and phencyclidine (detectable for 8 days).[21] In addition, urine tests are not 100% sensitive and specific. They were performed on a relatively small cohort and were obtained at one time point. Therefore some participants may have been misclassified as being truthful (false negative) or untruthful (false positive). Subjects were informed that the urine specimens provided may be tested for cotinine and drugs of abuse. Some of the participants could have been more honest in reporting smoking and drug use because they did not want their test results to belie their answers to these questions. Finally, testing did not include a screen for recent alcohol use.

Previous studies have found that computers may obtain more accurate information than that obtained in a face-to-face interview.[22, 23] Skinner and Allen[24] found that people were equally honest with computer-based interviews as with face-to-face or paper-and-pencil questionnaires in reporting use of alcohol, tobacco, caffeine, and drugs.

The fourth objective of the study was to compare responses to the Pregnancy Information Program with self-reported use of cigarettes, alcohol, and drugs of abuse obtained by a written questionnaire, completed as part of routine care in this prenatal clinic. Study participants did report significantly more drug and alcohol use during the computer interview; there was no difference in the rate of reported smoking. In the majority of instances, the discrepancy occurred because the participant denied the behavior during the written questionnaire and reported the behavior in the computer interview. However, there were a small number of exceptions, where a subject reported the behavior in the written questionnaire and denied it during the computer interview.

There are several possible explanations for the discrepancies between reports obtained from the two questionnaire modalities. The most likely explanation is that the women were more honest in reporting their behaviors during the computer interview. Conceivably women who were not smoking, drinking alcohol, or using drugs at the time they attended the prental class initiated these behaviors in the period between taking the written questionnaire and the computer interview. However, this seems unlikely. Available evidence indicates that a high percentage of women abstain from or reduce smoking and drinking alcohol soon after discovering they are pregnant.[25, 26]

Some of the participants may have reduced their high-risk behaviors as a result of the information provided during the educational class before receiving the computer program. This could account for the small number of persons who reported the behavior initially during the written questionnaire and failed to report the behavior during the computer interview. Some participants also may have misread or misunderstood the questions in either questionnaire, thus accounting for discrepancies.

The computer interview was offered in a setting of anonymity. Information provided during the computer interview was not made available to the patients' physicians; however, included in the on-screen information for the participants was a statement urging them to give the computer printout entitled "Provider Summary" to their physicians. An informal survey of providers conducted after this study was completed revealed that few printouts were actually received by providers. This is in contradistinction to the high percentage of women who stated they would give the report to their providers.

In a recent study of pregnant women[6] the authors found that those with a history of alcohol-related problems, determined by an elevated score on the Michigan Alcoholism Screening Test, were most likely to underreport alcohol consumption. In this study a large number of participants did not wish to disclose the results of their interviews to their physicians. The persons who were least willing to share their life-style information with their physicians were current drug and alcohol users. This finding supports the conclusion that the observed increased reporting of alcohol and drug use during the computer interview was attributable to its confidential nature.

Routine use of institution-specific computer software programs, such as described here, could provide personalized health risk information to all patients, including those women who do not report their behavior accurately to their health care providers. The software could be programmed to direct patients to an appropriate referral source and could optimize the use of existing services within the institution. The providers administering the interview would obtain prevalence data, which could be used to guide medical staff in making informed decisions about resource allocations. In addition, anonymous patient-interactive computer programs have demonstrated value in increasing dialogue between patients and their physicians in a general medical practice. Skinner et al.[8] found that patients were more likely to discuss life-style issues with their physicians if they received a computerized life-style assessment before seeing their physicians. If the Pregnancy Information Program were used as part of routine care, the provider summaries, when patients chose to share them, could serve as a focus for discussions regarding high risk for adverse pregnancy outcomes.

This study demonstrated that a confidential, computerized, patient-interactive assessment was valid in this patient population. Its use in prenatal clinics could enhance prenatal education programs and provide information useful for institutional planning and resource allocation.

We thank Clay Burchell, MD, Jan Ross, RN, and Jane Grubbs, RN, the staff of the Lovelace Department of Obstetrics and Gynecology, and the participants for their support of this study. We thank Gayle Sovereign for administering the program to participants; Harvey Skinner, PhD, David Paperny, MD, Diana Koster, MD, Marcia Messer, RN, and Pamela Palmer, PhD, for their contributions to the development of the Pregnancy Information Program; and Gary Simpson, MD, PhD, for his review of this manuscript.

Short-term variation in abnormal antenatal fetal heart rate records

P. Street, MRCS, G.S. Dawes, DM, M. Moulden, and C.W.G. Redman, MB
Oxford, England

In a retrospective study the relation of reduced fetal heart rate variation to fetal acidemia was analyzed with a computerized system for numeric analysis. Between 1983 and 1987, 78 pregnancies were identified in which at least one record of the fetal heart rate had very low long-term variation. The outcome was analyzed to determine the numeric criteria of fetal heart rate variation that most efficiently detect a fetus that will die (preterminal) or is dying (terminal). Because fetal compromise was found on occasion to be associated with a slow sinusoidal fetal heart rate rhythm that increased measures of long-term variation. It was necessary to define a new index of short-term fetal heart rate variation (the 1/16 minute epoch-epoch variation). This was closely related to long-term variation ($r = 0.9$) but provided better detection of preterminal records as judged by metabolic acidemia at delivery or intrauterine death. (AM J OBSTET GYNECOL 1991;165:515-23.)

Key words: Fetal heart rate variation, terminal fetal heart rate records, computer analysis, intrauterine death

Evaluation of the fetal heart rate (FHR) is a clinical test of well-being, that is based on empiric observations, of which many aspects are poorly understood. Grossly abnormal patterns have been identified by visual analysis but with large interobserver and intraobserver variation.[1-4] The degree of such variation is so great as to cast serious doubts on the accuracy of current guidelines. To overcome the problems of subjective analysis, we have developed a system for numeric analysis of the human FHR, with a small on-line computer.

The analysis depends on accurate fitting of the baseline and on simple techniques for measuring heart rate variation, accelerations, and decelerations. By quantifying signal loss, the quality of different recording systems can be assessed[5]; the introduction of a wide-range ultrasonographic transducer, combined with autocorrelation, improved record quality.[6]

Originally we started from the observations of Visser and Huisjes[7] that identified decelerative FHR traces as a cause for concern. However, the feature that was outstandingly associated with acidemia, on delivery by cesarean section in the absence of labor, proved to be a decline in FHR variation; hence the focus of this article. Its shortest component (beat-to-beat variation) is too small to be measured accurately by the present generation of FHR monitors and cannot be reliably estimated by external ultrasonographic monitoring.[8, 9] Measurement of longer-term FHR variation provided accurate information on the rest and activity cycles of the normal fetus[5, 10, 11] and evidence of compromise associated with chronic hypoxemia. An index of long-term variation, the mean minute range, was devised, in which the effects of decelerations are excluded to identify records that are otherwise flat. As gestational age advances, the mean minute range increases a little, but much less than the incidence of accelerations; at term its normal value is about 50 milliseconds corresponding to about 17 beats/min.[6] Abrupt changes in the magnitude of the mean minute range identify episodes of low or high FHR variation, coincident with changes in fetal rest and activity from 28 weeks' gestation onward. We have shown that a 5-minute episode of active fetal sleep, identified in this way, is a better index of health than reactivity defined in terms of FHR accelerations.[12]

FHR variation was much reduced in association with intrauterine growth retardation without acidemia.[13] This resulted from attenuation of the amplitude of variation rather than from prolongation of episodes of low variation.[14] The mean minute range was reduced from a normal value of 44 ± 1.5 milliseconds at 32 weeks to 20.6 ± 1.2 milliseconds, and this was associated with a decrease in fetal Pa_{O_2} measured at cesarean section before labor and with hypoglycemia, hyperalaninemia, and a rise in amniotic fluid erythropoietin as evidence of chronic hypoxemia.[15] Hypoxemia in these circumstances has been confirmed by cordocentesis.[16]

In these studies the attributes of the FHR of the

6/1/29775

chronically compromised fetus were defined, but the absence of acidemia at birth confirmed that the fetal state was not terminal. The concept of preterminal and terminal FHR records[7] has helped to identify the fetus that requires immediate delivery. In modern practice the qualities of the terminal trace cannot be studied formally because, once recognized visually, immediate intervention is required. However, to examine the limits of intrauterine survival in relation to FHR variation, we reviewed all cases encountered over 4 years (1983 to 1987) in which at least one record had an abnormally low mean minute range (<20 milliseconds), much less than the lowest with normal outcome.[17] We also identified a small number of fetuses with a terminal heart rate pattern who could not be delivered because of immaturity and who died in utero. In one a slow sinusoidal rhythm was superimposed on an otherwise flat FHR, in such a way as to yield a high mean minute range. We therefore explored the relation between short-term and long-term measures of FHR variation in preterminal and other records and derived a new index of short-term variation to improve diagnostic discrimination.

Methods

FHR records were taken with Hewlett-Packard model 8040 fetal monitors. The data were captured and analyzed by a microcomputer on line. From 1983 to 1985 the records were made with Nascom microcomputers.[5, 18] From 1986 these were progressively replaced with Apricot XEN microcomputers, which accessed the RS232 port of the HP8040. The archive of Nascom disks was transferred to the new system and reanalyzed. The date and time (to the nearest minute) of the start of the record was entered manually (Nascom) or automatically (Apricot XEN).

The analysis proceeded as follows. The autocorrelation function, generated by the fetal monitor as a measure to discriminate between background noise and valid signal, was sampled. Accuracy was further checked by an error algorithm.[19] Valid pulse intervals were averaged over epochs of 3.75 seconds (1/16 minute) and a baseline was fitted.[20] Signal loss was calculated as the proportion of epochs for which no valid pulse interval was available. The fetal monitor measures pulse intervals, not heart rate; therefore calculations of FHR variation were reported in milliseconds.

Large changes in heart rate from the baseline were identified as accelerations (>10 beats/min and 15 seconds) or decelerations (>10 beats/min and ≥1 minute, >20 beats/minute and ≥0.5 minute, or >25 beats/min and ≥0.25 minute). The area of decelerations was calculated as the number of lost beats,[21] and large decelerations were defined as having an area >20 lost beats. The temporal association of decelerations with uterine contractions (where present) and the lag time between peak contraction and FHR trough were recorded. In each minute the computer acquired 16 measurements of fetal pulse interval; each was averaged over a period of 3.75 seconds. The difference between minimum and maximum was calculated as the minute range. For a record of 25 minutes' duration, for example, there were 25 such values, whose average (the mean minute range) was calculated as an index of long-term FHR variation. Several adjustments were made. First, minutes in which a deceleration (defined above) occurred were excluded, so that decelerative variation did not amplify this index. In the same way minutes were excluded in which the FHR was wholly below baseline. Second, if the minute under consideration formed part of a prolonged acceleration, then the range was calculated from the baseline. These adjustments ensured that long-term variation (the mean minute range) was biased toward recording accelerative FHR variation, the main characteristic of the normal record.[22] There was a close correlation ($r = 0.97$) with the root mean square value of FHR variation.[6] Short-term FHR variation was calculated as the average of successive epochal (1/16-minute) differences, decelerations being excluded as for the calculation of long-term variation.

Certain decelerations and accelerations, with abrupt changes in FHR (>35 beats/min followed by an equally abrupt change in the opposite direction) were identified and excluded as unreliable evidence.[23] Decelerations and accelerations with high signal loss (>50%) also were eliminated as unreliable.

Episodes of high or low FHR variation were identified when in 5 of 6 consecutive minutes the mean minute range of pulse intervals was >32 or <30 milliseconds, respectively.[6, 24] If long-term variation was <22 milliseconds and there was no episode of high variation, the record was reanalyzed, with extra constraints on the construction of the baseline, to enable shallow decelerations to be identified (>5 beats/min and 0.5 minute) and their temporal relation to uterine contractions to be established. The choice of these criteria has been explained elsewhere,[5, 9, 10] and the application to fetuses of different ages has been checked by us[6, 11] and by joint studies with colleagues in other centers in Great Britain, The Netherlands, Canada, Italy, and the United States (unpublished observations). Basal heart rate was measured as the mean value during episodes of low FHR variation or, if no such episode was available, it was measured as the modal or peak value of pulse intervals (as previously described), calculated from the frequency distribution.[20] In this data set all records contained episodes of low FHR variation.

During the record the mother signaled all fetal movements with a hand-held button. Each epoch (3.75 seconds) containing one or more perceived movements was identified. The duration of the FHR trace was determined by the on-line analysis. If an episode of high variation was identified, with no large deceleration and at least one fetal movement or three accelerations, a message was displayed advising that recording may be stopped. Otherwise it lasted 60 minutes. The average record length in ordinary use was about 15 minutes. At the end of each record all FHR variables were printed, and if there were five or more records available on that patient, a synoptic display was presented in which the significance of the trend in short-term variation with time was calculated (e.g., Fig. 3). The computer program used was the same as that previously described,[6,15] with the addition of algorithms to exclude unreliable data[23] and to measure short-term FHR variation.

Clinical selection. We analyzed 7396 FHR records obtained from 2582 women from June 1983 through 1987, during which there were 23,010 births to 22,742 women in the John Radcliffe Hospital. The patients were monitored because they were identified as at high risk from medical disorders such as hypertension, diabetes, or renal disease; because of a poor obstetric history; or because of current obstetric problems, mainly proteinuric preeclampsia, or because the fetus was small for gestational age. These were cases of preterm placental vascular insufficiency, often associated with preeclampsia, in which closely judged decisions were needed to avoid premature delivery.

In 78 women the mean minute range was <20 milliseconds on at least one occasion. These women had a total of 961 antenatal FHR traces. The first record with a mean minute range (long-term variation) <20 milliseconds was defined as the index trace. The reasons for a subsequent decision to expedite delivery, by induction of labor or cesarean section, were classified before delivery as maternal (n = 9), maternal and fetal (n = 4), fetal (n = 39), or prophylactic (n = 16). In the last group neither maternal nor fetal safety was judged to be at immediate risk, that is, during the next 24 hours. Five women went into labor spontaneously. There were four intrauterine deaths and one other, very immature fetus died because the pregnancy had to be terminated urgently for reasons of maternal health at 27 weeks. The decision to deliver took into account the FHR trace, gestational age, and ultrasonographic estimate of fetal weight, a scan of fetal movements and amniotic fluid volume, and maternal condition. The principal guide to clinical management of the fetus has been the measurement of FHR variation.

Of the 57 women with proteinuric hypertension (Table I), 42 were treated with antihypertensive agents (38 with α-methyldopa, six of whom also received nifedipine), two received diazepam, and two were given a β-adrenergic-blocking agent.

Table I. Data on mothers and fetuses at time of index trace, on delivery, and after birth (mean ± SD)

Mother	
No.	78
Nulliparous	43 (55%)
Proteinuric preeclampsia	57 (73%)
Small-for-gestational-age	15 (19%)
Diabetes	1 (1%)
Maternal age (yr)	28.1 ± 7.9
FHR record (index trace)	
Gestational age (days)	221.5 ± 34.2
FHR variation (msec)	
Long-term	16.7 ± 2.7
Short-term	3.0 ± 0.6
Delivery	
Gestational age (days)	230 ± 34.3
Intrauterine deaths	5
Total live-born	
Vaginal delivery	16 (4 acidemic)
Cesarean section	57 (4 acidemic)
Umbilical artery blood pH	7.22 ± 0.02
Neonatal outcome	
Live-born	73
Neonatal deaths	4
Hyaline membrane disease	30 (41%)
Hypoglycemia	26 (36%)
Patent ductus arteriosus	18 (25%)
Mortality	9 (11%)

Acidemia on delivery was defined as an umbilical arterial pH <7.12 and a base deficit >12 mmol/L. Umbilical arterial and venous blood was sampled; measurements were made at 37° C (ABL2 Radiometer, Copenhagen). Neonates <10th percentile of birth weight for gestational age and gender[25] were defined as being small for gestational age. Hypoglycemia was defined as a blood glucose level <1.11 mmol/L for an infant <2.5 kg, otherwise as <1.66 mmol/L. Hyaline membrane disease was defined as an immature infant with increased breathing, an expiratory grunt, rib recession on inspiration, cyanosis, and a chest x-ray film with diffuse granularity and an air bronchogram.

This study is retrospective and describes the evolution of methods that were not anticipated but have evolved as clinical and analytic experience has grown. The ultimate hypothesis was that a reduced FHR variation characterized the hypoxemic and acidemic fetus.[7,13,15] Hence statistical tests were used to confirm the anticipated relation between FHR variation and fetal arterial pH or base deficit. The Student t test was used to compare mean values, and the significance of trends in FHR variation with time was calculated from the slope of the regression line.[26] Nonparametric measures (such as the Mann-Whitney U test) also were used where there was evidence of nongaussian distribution.

Results

Clinical data and outcome. The clinical details are shown in Table I. The mean gestational age at which the index FHR trace was taken was just under 32 weeks,

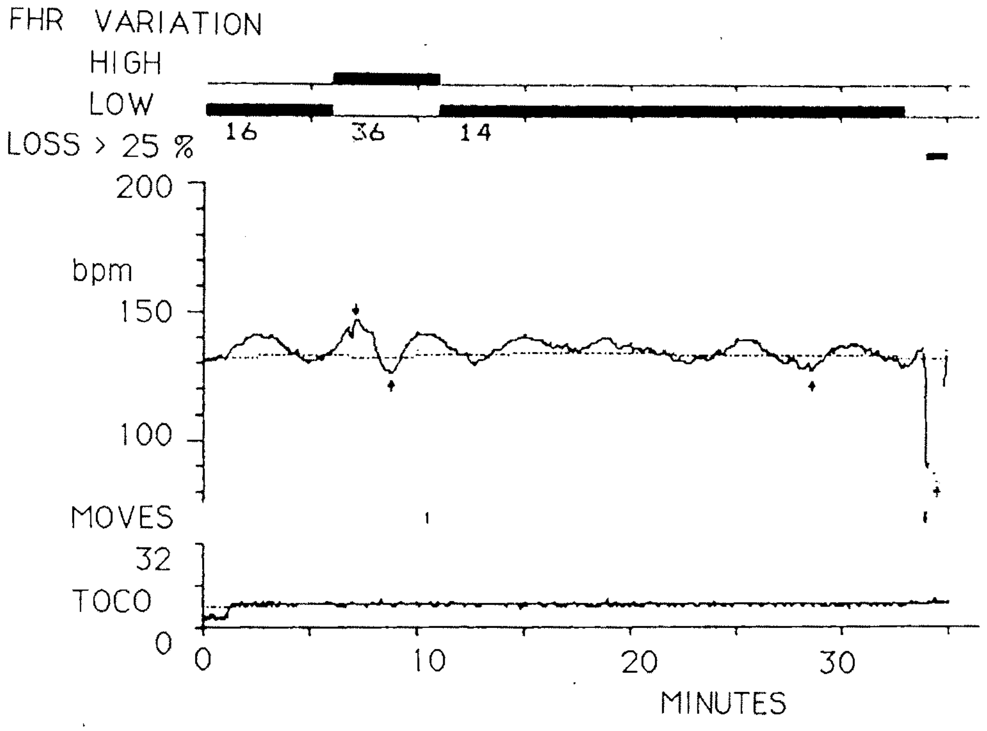

Fig. 1. Record at 28 weeks showing slow sinusoidal oscillation imposed on otherwise flat trace. Long-term variation was 18.3 milliseconds; short-term, only 1.6 milliseconds.

No.	17	19	42
Days to delivery	6 (1-74)	2 (0-20)	3 (0-37)
Acidemia at delivery*	2	1	5
Intrauterine deaths	4†	1	0
Neonatal deaths	1	3	0

*pH <7.12 and base deficit >12 mmol/L, four of which were delivered after labor (three at >32 weeks).

†There was one termination of pregnancy for reasons of maternal health at 27 weeks. Two infants had Down's syndrome; one died neonatally. There were no other congenital abnormalities.

but the range was from 24 weeks 1 day to 37 weeks 6 days. One pregnancy was terminated for maternal reasons at 27 weeks. The four intrauterine deaths were predicted, but the fetuses were not delivered because of extreme prematurity.

The total of intrauterine and neonatal mortality was high (11.5%), as would be expected in this high-risk group. More than half of the deaths occurred in those in whom the index trace was taken at <28 weeks, and there were none when it was taken after 32 weeks (Table II). Table II also shows the incidence of acidemia (as defined) at delivery, analyzed by the gestational age at the index traces. Acidemia was associated with labor (four cases) or with a single FHR trace, after which delivery by cesarean section was done at once (two cases, short-term variation very low, 2.1 milliseconds in both instances), or with an exceptionally rapid fall in FHR variation (two cases). All stillbirths were anticipated as terminal FHR traces. Twenty-seven fetuses were <30 weeks' gestation when the index trace was taken; nevertheless, pregnancy was safely prolonged in 17 (63%) by an average of 17 days.

Short- and long-term FHR variation. In one patient an FHR record was encountered with a single slow sinusoidal oscillation imposed on an otherwise flat trace (Fig. 1). The amplitude of the oscillation was so large that an episode of high variation (usually a reliable indicator of normality) was identified at 6 to 11 minutes (amplitude, 36 milliseconds), and there were two episodes of low variation (16 and 14 milliseconds). The ominous significance of the record was appreciated at the time, but it was decided not to deliver the fetus because it was small (<500 gm) and immature; it died in utero during the next 24 hours. This trace demonstrated that an episode of high long-term FHR variation could occur in an otherwise terminal trace, but the variation was of a distinctive type not seen in normal records. This stimulated a reconsideration of long-term

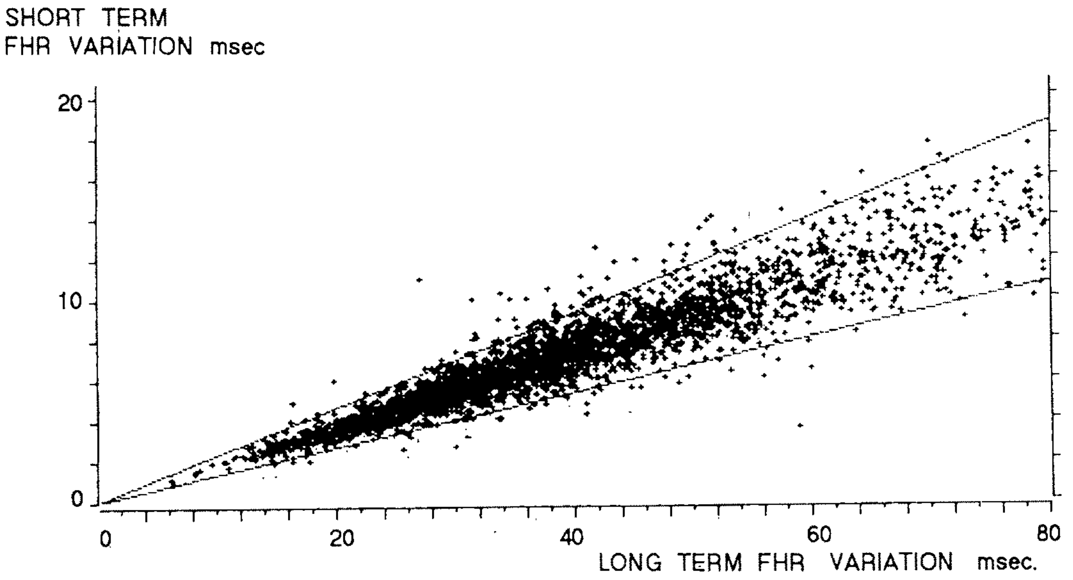

Fig. 2. Relation between short- and long-term variation in 3074 FHR traces, including 961 of this study. Mean ratio of short- to long-term variation was 0.18; *lines* are ±2 SD about mean.

variation as the only measure of FHR variation, so that the identification of terminal traces could be made more precise.

A new statistic of short-term variation was calculated as the average of the differences in mean pulse intervals in consecutuve epochs lasting 3.75 seconds (epoch-to-epoch variation). The ratio of short- to long-term FHR variation was analyzed in 2113 consecutive normal clinical records (short-term variation, 7.8 ± 3.01 milliseconds, mean ± SD) and in the 961 records of this study (short-term variation, 4.8 ± 1.85 milliseconds, mean ± SD). Because the distribution of ratios was similar, the results were combined. Fig. 2. shows this relationship, the lines being ±2 SD from the mean. The correlation coefficient was 0.90. The ratio (mean ± SD) of short-term to long-term variation was 0.183 ± 0.024; in contrast, the values for short- and long-term variation for the case illustrated in Fig. 1 were 1.6 and 18.2 milliseconds, respectively, with a ratio of 0.088, >2 SD below the mean.

We then sought how often such single sinusoidal rhythms of large amplitude occurred. There were seven records with short-term variation >2 SD below the mean value predicted from long-term variation, and with long term variation <30 milliseconds, five had simple (that is, single) sinusoidal patterns of large amplitude. The incidence of such slow sinusoidal traces was 1.6 per 1000 records (in the whole population, 7396 records) but one in nine (5/43) terminally in fetuses that were delivered by cesarean section for fetal (or fetal and maternal) reasons or died in utero. Of the three delivered alive, two were severely acidemic (pH 6.9 to 7.01; base deficit 14 mmol/L). Thus calculating the ratio of short- to long-term variation has identified rare FHR traces with slow single sinusoidal oscillations superimposed on low short-term variation. Short- and long-term variation was calculated for all records described in this report.

The next step was to analyze the relationship between the new index of short-term variation and umbilical arterial blood acid-base status at delivery and to determine the values characteristic of a terminal or near-terminal trace. For the purpose a subset of the 78 cases was selected that had at least one trace with short-term variation <3 milliseconds. This limit was chosen from a knowledge of the distribution of short-term variation in normal traces, as well as of the 961 study records, and corresponds to a mean minute range of 16.4 milliseconds (Fig. 2). There were 44 such cases (40 live births; Table III). When short-term variation decreased below 2.6 milliseconds, umbilical arterial pH was decreased and base deficit was increased, suggesting that the fetus was becoming acidemic and the record might be preterminal. This was consistent with observations on the four intrauterine deaths, for which the short-term variation was 0.9 to 2.5 milliseconds in the last trace within 24 hours of death.

The possible influence of drugs on basal FHR, FHR variation, and outcome was examined. The mothers of the four fetuses that died in utero had not received drug treatment. Nor had six of the eight found to be acidemic (pH <7.12 and base deficit >12 mmol/L) on delivery; the other two had received α-methyldopa only. In 37 patients treated with α-methyldopa and 28 untreated patients, there were no statistically significant differences between the two groups in basal FHR, FHR variation, or arterial base deficit on delivery.

Trends in short-term FHR variation before deliv-

ery. In 44 (56%) of the 78 patients there were seven or more records on file, which could be used to analyze the trend with time in short-term FHR variation. Twenty-eight of the 44 pregnancies were terminated for fetal (or fetal and maternal) reasons, 10 prophylactically to avoid further risk (all but one at 36 to 37 weeks' gestation) and five for maternal reasons only; there was one intrauterine death. In nine cases the short-term variation fell significantly ($p < 0.05$) during the last 2 weeks before delivery. In four pregnancies it increased to a significant extent, and in the remaining 31 there was no significant trend with time. Fig. 3, *A*, shows a rapid fall in short-term variation (−0.58 millisecond per day). Fig. 3, *B*, shows a slower fall over a 2-week period. The most rapid fall (by −1.01 millisecond per day down to 2.2 milliseconds terminally) was observed in seven records taken over 4 days in a fetus acidemic on delivery by cesarean section at 28 weeks. Fig. 3, *C*, illustrates the converse, a progressive improvement, shown by a significant rise in short-term FHR variation (+0.20 millisecond per day; $p < 0.05$) over 9 days with more fetal movements; the pregnancy was terminated by cesarean section at 28 weeks for maternal reasons (symptomatic proteinuric preeclampsia). The proportions delivered for fetal reasons were 89%, 55%, and 0% associated with falling, unchanged, or rising trends in short-term FHR variation. The umbilical arterial blood pH of those delivered after a fall in short-term FHR variation was significantly lower (7.20 ± 0.019) than that of the rest (7.27 ± 0.013, $p < 0.01$) Fig. 3 also illustrates the relatively small changes in basal heart rate with time in such circumstances.

In 13 of these 44 patients there was an abrupt terminal reduction in fetal movements or long-term FHR variation (usually both), even when the trend over the last few days had not been remarkable in either direction.

Seven fetuses were delivered for fetal reasons at once (mean short-term variation, 2.5 ± 0.20 milliseconds) at 29 weeks to 33 weeks 6 days as a result of only one or two FHR records. The FHR traces of three of these fetuses had no decelerations, suggesting that the presence of decelerations may be an unreliable guide to a preterminal or terminal fetal state. The umbilical arterial pH (mean ± SE) on delivery (in all seven) was 7.09 ± 0.06). Two of these fetuses were asphyxiated (pH <7.12 and base deficit >12 mmol/L), both with Apgar scores of 2 at 1 minute and 9 at 5 minutes.

Drugs. No maternal medication had been given to the four fetuses that died in utero or to six of the eight that were acidemic (pH <7.12 and base deficit >12 mmol/L) on delivery. Multivariate analyses on data from the 38 women who received α-methyldopa as compared with the remainder, with consideration of gestational age, showed no effect on basal heart rate, FHR variation, or outcome. Similar analyses on the smaller number who received nifedipine also showed no effect.

Comment

We have sought to define more precisely the limits of FHR variation in the terminal traces of fetuses about to die because of increasing metabolic acidemia. Before the study began, we did not measure short-term variation but only the mean minute range (long-term variation). However, this index failed to detect a terminal trace with a sinusoidal pattern superimposed on a heart rate with very low short-term variation. Sinusoidal patterns occurred in one of nine terminal traces. This led us to examine measurements of short-term variation. Very-short-term FHR variation (literally beat-to-beat)

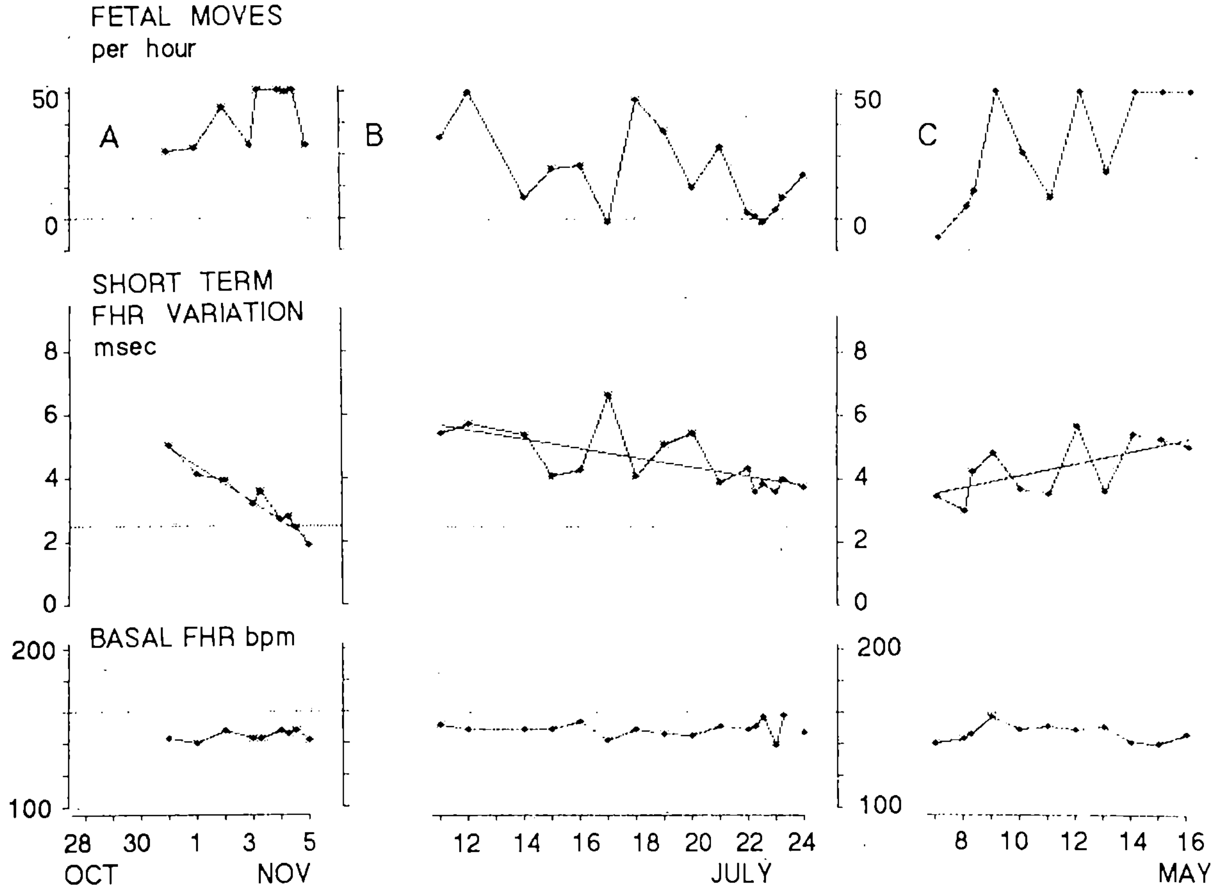

Fig. 3. Three synoptic displays of number of fetal movements per hour *(top)*, of short-term FHR variation *(middle)*, and of basal heart rate *(bottom)*. *Horizontal lines* are drawn at 10 movements per hour, short-term variation 2.5 milliseconds, and basal heart rate 160 beats/min. **A,** From pregnancy at 32 weeks with significant downward trend in variation (−0.58 msec/day; $p < 0.01$). **B,** Slower decline ($p < 0.01$) between 32 and 34 weeks. **C,** Significant upward trends in variation (+0.20 msec/day; $p < 0.02$) at 27 to 28 weeks' gestation; delivery was undertaken for maternal reasons. In no instance was there metabolic acidemia on delivery.

can be measured accurately from a scalp clip electrocardiogram in labor but not by ultrasonographic Doppler methods. Even from a scalp clip the normal value is low, only 2.1 ± 0.2 milliseconds[8] (mean pulse interval variation ± SE) or 1.98 ± 0.32 milliseconds[9] in two separate studies of normal fetuses during labor. This is at the limit of accuracy of measurement. The FHR cannot be detected reliably, between 26 and 34 weeks' gestation, by abdominal electrocardiogram. This precludes the accurate measurement of beat-to-beat variation. The problem is aggravated by the use of autocorrelation, a process that uses two successive pulse intervals to achieve an estimate of heart rate and so reduces (literally) the value of beat-to-beat FHR variation.[9]

We therefore defined a new measure of short-term variation as that between successive 3.75-second (1/16-minute) epochs during which valid FHR values are averaged (epoch-to-epoch variation). There are on average nine fetal pulses during each epoch at 144 beats/min. Epochs lasting 1/16 minute were first used in 1979 to reduce the data as much as possible (by a factor of 9) without compromising detection of brief changes in FHR from the baseline (small accelerations or decelerations) and to minimize the effect of signal loss. The epoch-to-epoch variation uses the least interval compatible with our data collection system, yet the mean value is sufficiently large to provide a good measure of short-term variation as it declines before death in utero.

The mean value of epoch-to-epoch variation for normal fetuses near term (corresponding to a long-term variation of 50 milliseconds, Fig. 2) is about 9 milliseconds. We have previously demonstrated that a mean minute range >30 milliseconds is associated with normal outcomes[17] and that it must fall to <20 milliseconds before there is evidence of chronic compensated hypoxemia at delivery by cesarean section in the absence of labor.[15] The limit of 20 milliseconds was used to define the population included in this study. A mean minute range of <15 milliseconds identified most of the compromised fetuses but with the important exception of five fetuses with slow sinusoidal FHR patterns, in whom the problem could be detected numerically only by measuring short-term variation. In a restricted sample of 44 cases with reduced short-term FHR variation, a final measurement of 2.5 milliseconds identified all terminal cases and three of the four preterminal cases with metabolic acidemia at birth. In five further fetuses encountered since the study was closed in 1987, short-term variation was 0.9 to 2.2 milliseconds within 24 hours of death; delivery was not undertaken because of extreme growth retardation and immaturity.

All such thresholds are empiric, widely used in medicine and necessary for convenience; they do not distinguish biologic differences in an absolute way but only define useful landmarks. In this study our purpose was to develop an objective measure of the terminal FHR trace. Given the small numbers, the constraints imposed by clinical interventions, and the fact that a few flat traces can have causes other than increasing metabolic acidemia, it should be clear that no claim can be made of an absolute measure of fetal respiratory status. However, no other noninvasive method can provide equivalent information about the fetus so objectively.

It has been considered that a reactive FHR is the most reliable guide to normality. We have shown that an alternative and better measure is identification of a short period in which the minute range is consistently high.[12, 17, 22] This is both more economical in time and more sensitive than the nonstress test. When combined with measurement of short-term FHR variation, it also follows that a contraction stress test is not required.

Gross reduction of FHR variation, unaccompanied by decelerations and with normal blood gas values at delivery, also has been described in some cases of anencephaly, after accidental fetal decerebration,[27] in two cases of fetal brain death,[28] and as a result of maternal administration of drugs. A similar situation was reported in fetal lambs after destruction of the brain above the cervical spinal cord, i.e., including the pons and medulla but not otherwise.[25] In these circumstances the baroreflex was lost. Thus identification of a very flat FHR trace is compatible with a number of diagnostic conclusions, of which the commonest (chronic, possibly compensated hypoxemia and incipient acidemia associated with fetal growth retardation and proteinuric preeclampsia) is now estimated to include 95%.

Our conclusions are provisional and their validity needs to be tested prospectively. The use of computerized analysis confers the major advantage of consistency in interpretation. Loss of FHR variation, which is impossible to estimate visually, needs to be extreme before fetal health is jeopardized.

We thank Mrs. June Jennings who recorded most of the traces, and many midwives and other colleagues for their help with the collection of data.

Maturation of the uterine cervix by repeated intracervical instillation of prostaglandin E_2

Jacques M. Milliez, MD, Denis Jannet, MD, Claudine Touboul, MD,
Mahfoudh El Medjadji, MD, and Bernard J. Paniel, MD
Créteil, France

An attempt was made to ripen the uterine cervix in 100 high-risk pregnancy patients (pregnancy between 34 to 41 weeks' gestation), with the use of intracervical instillations of 0.25 mg of prostaglandin E_2 mixed with a tylose gel. The maturation process was repeated every 48 hours. Forty-nine patients were delivered of infants after the first maturation and 51 patients required between two and nine instillations. In patients requiring multiple instillations, the mean delay between the first procedure and delivery was 9 ± 4 days (range, 2.4 to 16 days). Among the 59 nulliparous women, only 23 were delivered of infants after a single maturation and 36 required multiple maturations ($p < 0.02$). When the group of patients who were delivered of infants after a single maturation process was compared with the group requiring multiple maturations, no difference could be seen with regard to age, term of pregnancy, or Bishop cervical score at the time of inclusion in the study. The myometrial activity and the onset labor induced by prostaglandin E_2, were similar in both groups. Fetal heart rate decelerations occurred in 16.3% (8/49) of the patients with single maturations and in 17.6% (9/51) of the patients who required multiple maturations. The outcome of the pregnancy and the rate of cesarean sections (24% and 27%) were similar in both groups. No patients required cesarean sections because of failed induction of labor. Cervical ripening after repeated applications of 0.25 mg of prostaglandin E_2 seems to be safe for the fetus, providing that the patient is closely supervised. (AM J OBSTET GYNECOL 1991;165:523-8.)

Key words: Prostaglandin, maturation, cervix, pregnancy

Intracervical application of prostaglandin E_2 (PGE_2) is now advised when maturation of the uterine cervix is necessary for the induction of labor in high-risk pregnancies.[1] Usually, the recommended protocol consists of instilling a single dose of 0.5 mg of a PGE_2 gel into the cervix, followed 12 hours later, if regular uterine

contractions do not ensue, by the induction of labor with intravenous oxytocin.[2-6] Other application sites for PGE_2 gel have been tried, namely in the extraamniotic space or the posterior vaginal fornix,[7, 8] and larger doses of PGE_2 have been instilled into the cervix.[9, 10] However, in each of these previous attempts the use of the PGE_2 gel was limited to a single maturation of the cervix and if labor was not established in the mean time, induction was carried out 12 hours later.

Prospective multicentric randomized controlled trials[4, 11] and a double-blind controlled trial,[12] have clearly shown that a single dose of 0.5 mg of PGE_2 gel is superior to placebo in maturing the uterine cervix. However, the disadvantage with a single application of the PGE_2 gel is that when the maturing effect is insufficient, labor may be induced on a still unfavorable cervix 12 hours later. The failure rate in the induction of labor and the need of cesarean sections are then nearly as high as when the cervix has been ripened with placebo.[12]

Very few studies have attempted repeated maturations of the cervix when the first dose of PGE_2 appeared to be insufficient,[13, 14] and all of them were limited to a second application of the PGE_2 gel 6 or 12 hours after the first. Because the need for cervical maturation before induction of labor nearly always applies in high-risk pregnancies, the reaction of the endangered fetuses to repeated applications of PGE_2 is obviously a matter of concern.

Therefore this study was designed to test the effect of repeated maturations with PGE_2 gel on the fetus in high-risk pregnancies. The aim in all cases was to obtain a favorable cervix before the induction of labor. The outcome of 49 deliveries obtained after a single maturation was compared with the outcome of 51 pregnancies subjected to repeated applications of the PGE_2 gel.

Material and methods

A total of 100 high-risk pregnancy patients from our antenatal clinic were included in the study. The investigation was approved by the local Human Investigation Committee and informed consent was obtained. In all cases either the maternal or the fetal conditions justified induction of labor (Table I). Patients with breech presentations, premature rupture of membranes, previous cesarean sections, and uterine contractions were excluded from the study. All patients had a cervical Bishop score[15] less than 5 at the time of the first maturation.

All procedures were performed in the labor ward. Each patient was checked for cervical score and monitored over a period of 30 minutes to ensure that the fetal heart rate (FHR) was normal and that there were few or no uterine contractions (fewer than three per 30 minutes).

Cervical maturation was established by adding 0.25 mg of dinoprostone (Prostin E_2, Upjohn Co., Paris), to 3 ml of tylose gel prepared immediately before use. The patient was placed in a slight Trendelenburg position; the gel was gently instilled into the cervical canal with a size 8F plastic catheter, starting at the internal os and progressively withdrawing the catheter. Cardiotocography was maintained in the labor ward for at least 2 hours afterward, and was continued in cases of persistent uterine contractions or established labor.

The Bishop score was assessed by the same person, 2, 24, and 48 hours after instillation of the gel. Cardiotocography (duration, 30 minutes) was repeated every 12 hours until the following maturation procedure 48 hours later. The investigation was interrupted within the 48 hours after the first maturation for three reasons: onset of labor before the following maturation procedure; rapid deterioration of the fetal or maternal condition requiring prompt delivery (irrespective of the cervical status); improvement of the Bishop score to 6 or more, allowing a safe induction of labor with oxytocin.

With exception to the previous three circumstances, a second instillation of 0.25 mg of PGE_2 gel was given 48 hours after the first and was repeated every 48 hours thereafter under the same conditions. The onset of labor, an aggravation of the maternal or fetal condition requiring induction of labor, or an improved Bishop score up to at least 6 allowed a break in the sequence of repeated maturations of the cervix.

All the 100 patients who needed induction received a first application of the gel. Those who labored spontaneously, had a Bishop score greater than 6, or experienced maternal or fetal distress were included in the group with the single gel application and the remainder were in the group with multiple gel applications.

For each maturation the following parameters were recorded: maternal blood pressure, heart rate, and temperature. Cardiotocographic data were analyzed as follows: uterine contractions were recorded with a numeric score[16] as absent (0), mild and irregular (1), pain-

ful and irregular (2), or painful and regular (3); FHR decelerations were classified as absent, mild, moderate, or severe, according to their intensity and duration.[17]

Maturations were performed irrespective of the term of pregnancy. Fifteen patients had a term of pregnancy <37 weeks at the time of the first maturation, with three patients being at 34 weeks' gestation.

Statistical analysis. All the results were expressed as means with SD. Comparison of the means was carried out by analysis of variance. If the Fisher test was significant ($p < 0.05$), variables between the series were then compared with the Student t test (significant p value < 0.05).

Results

A total of 201 maturation procedures were performed on 100 patients: 49 were delivered of infants after one maturation and 51 required multiple maturations.

Termination of pregnancy. The mode of delivery, indication for induction of labor or cesarean section, and the mean delay between gel application and onset of labor are represented in Table II, according to the number of maturations applied.

Among the 51 patients who required multiple maturations, 12 patients had three, three patients had four, four patients had five, two patients had six, one patient had seven, and one patient had nine maturations.

No undesirable side effect of prostaglandins (i.e., nausea, vomiting, or diarrhea) was observed in any of the 201 maturation procedures performed.

Myometrial response to the PGE$_2$ gel. In 201 maturations, no myometrial activity was recorded in 30 patients.

In 130 patients, uterine contractions were exerienced but lasted <2 hours after the instillation of the gel. Table III indicates the score of the uterine contractions observed for each group of single or multiple maturations. Contractions produced moderate or severe FHR decelerations in six patients. Labor was immediately induced, resulting in three vaginal deliveries and three cesarean sections for persistent fetal distress (repetitive slowing of FHR and meconium-stained amniotic fluid). Type 3 uterine contractions were recorded for 11 patients and were resolved spontaneously. Myometrial activity also stopped spontaneously with no further consequences for the remaining 113 maturations.

In 41 maturations, myometrial activity lasted longer than 2 hours. In 13 patients, all with a single maturation, myometrial activity did not resolve and resulted in established labor. Labor was induced for five other patients because of persistent painful uterine contractions and for two patients because of FHR decelera-

‡$p < 0.02$.

tions; all resulted in vaginal delivery. For the 21 remaining maturations, uterine contractions stopped spontaneously and no further consequences occurred in a period of 4 to 24 hours.

Cervical response to PGE_2 gel. For the 100 patients included in the study the Bishop score increased from 2.6 ± 0.9 on the day of the first maturation to 6.3 ± 1.3 at the induction or the spontaneous onset of labor. An improvement in the cervical score up to 6 allowed a safe induction of labor in 46 patients, 20 after a single maturation, and the remainder of patients after repeated maturations. In addition for 32 patients (16 in each group), labor had to be induced because of the maternal or fetal condition. Overall, 78 inductions of labor were performed, and all proceeded successfully to an established labor. Spontaneous onset of labor occurred in the remaining 22 patients.

Fetal response to PGE_2 gel. In 17 of 201 maturations and 14 of 100 patients, FHR decelerations occurred before the onset of labor. These decelerations were mild in 10 patients, moderate in four, and severe in three. They disappeared with lateral recumbency in nine patients. For eight patients they led to the induction of labor, resulting in four vaginal deliveries and four cesarean sections because of persistent fetal distress. For these 14 neonates the mean birth weight was 2217 ± 290 gm, 10 of whom had a birth weight below the 10th percentile. The mean 1- and 5-minute Apgar scores for these 14 neonates were 7.2 ± 2.1 (range, 2 to 10) and 8.6 ± 2.1 (range, 5 to 10), respectively.

For three patients FHR decelerations appeared after the first 2 hours of maturation (6, 9, and 47 hours, respectively), leading to conservative management in one case and induction of labor in two.

Comparison between the groups of single and multiple maturations (Table IV). There were 23 nulliparous women (46%) in the group with single maturation and 36 nulliparous women (70.5%) in the group with multiple maturations ($p < 0.02$). However, no difference could be seen between both groups when compared for age, term of pregnancy, or Bishop score at the time of inclusion in the study. FHR decelerations induced by the PGE_2 gel occurred in 16.3% of the patients (8/49) with one maturation, and 17.6% of the patients (9/51) with multiple maturations. The number of patients who required induction of labor because of FHR decelerations, persistent uterine contractions, or improved cervical score and the number of patients who experienced spontaneous labor after maturation were similar in both groups.

Twenty-seven patients had cesarean sections, 12 after a single maturation and 15 after repeated maturations. The number of cesarean sections for acute fetal distress was similar in both groups (10 and seven, respectively). The other cesarean sections (two and eight, respectively) were indicated for fetopelvic disproportion.

The outcome of pregnancy, birth weights, growth retardation below the 10th percentile, 1- and 5-minute Apgar scores, were not different between both groups of patients.

Comparison between nulliparas and multiparas (Table V). Twenty-six of the 41 multiparas (63.4%) were delivered of infants after one maturation, whereas only 23 of the 59 nulliparas (38.9%) were so ($p < 0.02$). Multiparas were older than nulliparas (30.9 ± 6.1 vs

Comment

When labor is induced 12 hours after cervical ripening with a local application of 0.5 mg of PGE_2, failed induction ranges between 13.5% and 16%[4, 12] and can possibly lead to avoidable cesarean sections. Higher doses of PGE_2 increase the liability of unwanted uterine contractions or hyperstimulation.[9, 10] Therefore there is a need for a new approach to the local application of PGE_2, for example, sequential intracervical instillations. Because this study does not include a controlled series, the superiority of repeated PGE_2 low-dose applications over other methods of cervical ripening cannot be assessed, but the potential hazards, particularly with regard to the fetus, can be evaluated.

The main finding of our study is that repeated maturations do not provoke any greater risk of distress for the fetus or the neonate than a single maturation, providing that they are closely supervised after each maturation. In the 201 maturations performed, 8.4% (17/201) were complicated by FHR decelerations, which is also the rate reported after cervical ripening with 0.5 mg of PGE_2 and after intracervical instillation of a placebo gel.[11] However, the frequency of FHR decelerations was not different for the patients with one maturation (16.3%) or multiple maturations (17.6%). The outcome of pregnancy was also similar in both groups of patients, and in spite of a population with high-risk pregnancies, no particular detrimental effect of multiple maturations was recorded for the neonates, even after as many as seven or nine repeated maturations.

It is surprising that the reduction of the dose of PGE_2 from 0.5 mg to 0.25 mg did not prevent myometrial activity during cervical ripening. Cervical ripening with 0.5 mg of PGE_2 induces 4% to 12% incidence of myometrial hyperstimulation,[2, 5, 6, 11, 12] and entails 0.5% to 3% cesarean sections for acute fetal distress. Myometrial hyperstimulation occurs more frequently after extraamniotic application of the PGE_2 gel[4] and has been reported after cervical application of a placebo gel.[4, 11, 12] Granström et al.[18] found that proper intracervical instillation of 0.5 mg of PGE_2 gel, in contrast with extraamniotic or vaginal application, induces cervical ripening without significant myometrial activity. Our results are at odds with the findings of Granström et al. because after intracervical instillation of only 0.25 mg of PGE_2, uterine contractions occurred in 85% of the maturations (171/201) and in 20% of the patients myometrial activity persisted beyond 2 hours. However, tocolysis was never used because β-sympathomimetic agents administered with PGE_2 may lead to untoward effects.[11]

The aim of repeated maturations with PGE_2 was to obtain in all instances a favorable cervix before planned induction of labor. After application of 0.5 mg of PGE_2, labor is established before oxytocin induction in 38.5% of the patients.[12] In this study, the PGE_2 gel acted beyond a simple ripening effect of the cervix and was sufficient enough to induce labor in 22% of the patients. Whereas failed induction of labor occurred in 13.5% to 16% of the patients after maturation with a single dose of 0.5 mg of PGE_2,[4, 12] no failure was recorded for the 78 inductions of labor in this study and all proceeded successfully to an established labor with a cervical dilatation of ≥3 cm. It is worth noting that 15% of our patients had their first maturation before 37 weeks of amenorrhea (three as early as 34 weeks), whereas all previous studies[1-14] dealt with term pregnancies.

A puzzling finding of this study was the difference in sensitivity of the cervix and myometrium to PGE_2 between the 49 patients who were delivered of infants after a single maturation and the 51 patients who required multiple maturations. Of course there were significantly more nulliparous patients in the group of multiple maturations. However, both groups (single and multiple maturations) along with the two groups of nulliparas and multiparas were otherwise similar with regard to the term of pregnancy and to the Bishop score at the time of the first maturation. Myometrial contractility and cervical distensibility are subject to concordant endocrine regulation, involving estrogen: progestogen ratios, prostanoids, and relaxin.[19, 20] Maturation of the cervix implies changes in the structure and biochemistry of the connective tissue, namely dissolution of the collagen fibrils, diminution of the dermatan sulfate, and increase in hyaluronic acid and water content. Therefore induction of labor probably needs to be supported by more accurate means to measure cervical compliance and distinguish parity than the current clinical evaluation.

count six

The innovative efforts made by Organon in gynaecology are making such headway that its broad product portfolio now approaches completeness:

1 oral contraceptives
2 hormone replacement therapy
3 gynaecological disorders
4 obstetrics
5 fertility stimulation
6 diagnostics

ORGANON IN GYNAECOLOGY

striving for completeness

Organon

the human signature

The extensive portfolio of gynaecological products now available from Organon is the result of a tradition of innovation plus an appreciation of the needs of both women and the medical profession. Generations of women have benefited from the fruits of this research – from oral contraceptives, to hormone replacement therapy and gonadotrophins. Organon's fertility stimulating products have for generations been relied upon throughout the world. Living proof of Organon's commitment to worldwide gynaecological service.

FEMSTAT® PREFILL ℞
(butoconazole nitrate) VAGINAL CREAM 2%

BRIEF SUMMARY

INDICATIONS: FEMSTAT® (butoconazole nitrate) vaginal cream 2% is indicated for local treatment of vulvovaginal mycotic infections caused by Candida species. Confirm the diagnosis by KOH smears and/or cultures. FEMSTAT can be used with oral contraceptives and antibiotics. It is effective in non-pregnant women and during the second and third trimesters of pregnancy.

CONTRAINDICATIONS: FEMSTAT is contraindicated in patients hypersensitive to any of the ingredients.

PRECAUTIONS: General: If clinical symptoms persist, repeat microbiological tests to rule out other pathogens and confirm the diagnosis. Discontinue drug if sensitization or irritation occurs.

Information for the Patient: Do not discontinue prematurely during menstruation or because of symptomatic relief.

Carcinogenesis: Animal studies have not been done.

Mutagenesis: Mutagenicity studies were negative.

Impairment of Fertility: Animal studies showed no impairment of fertility.

Pregnancy Category C: Adverse effects were noted in animals treated with high oral doses. No studies were done in women during first trimester. Patients in the second or third trimester have shown no adverse effects attributable to the drug.

Nursing Mothers: Use with caution.

Pediatric Use: Safety and efficacy have not been established.

ADVERSE REACTIONS: Vulvar/vaginal burning in 2.3% of patients, vulvar itching in 0.9%, discharge, soreness, swelling, itching of fingers each in 0.2%. Complaints caused 1.6% to discontinue drug.

DOSAGE AND ADMINISTRATION: Non-pregnant Patients: The recommended dose is one applicatorful of cream (approximately 5 grams) intravaginally at bedtime for three days. Treatment can be extended for an additional three days if necessary.

Pregnant Patients (second and third trimesters only): The recommended dose is one applicatorful of cream (approximately 5 grams) intravaginally at bedtime for six days.

CAUTION:
Federal law prohibits dispensing without prescription.

CHIEF,
OBSTETRICS/GYNECOLOGY

Newton-Wellesley Hospital, a 340-bed Tufts affiliated community teaching hospital, located less than 10 miles west of Boston, is conducting a search for a Chief to head the Department of Obstetrics & Gynecology. This position is full-time including practice opportunities.

Candidates must be board certified in Obstetrics and Gynecology and have strong clinical interests and skills, a commitment to family-centered patient care, management skills, and an ability to lead an active educational program geared to the needs of a rapidly growing department. Interest and expertise in one of the subspecialties of Obstetrics and Gynecology is preferred.

There are currently 3600 deliveries per year at the Newton-Wellesley Hospital, with continued growth anticipated. The Maternity Facility consists of a 20-bed LDRP Unit, 6 LDR suites, 2 C-section/high risk delivery suites, 2-bed PACU and 24-bed post partum unit, and an antenatal testing unit. This service is supported by a 12-bed, Level II, special care nursery, as well as full-time neonatology and anesthesia coverage.

The successful candidate will be responsible for the ongoing clinical, administrative, and teaching activities for the department, as well as for the direction of its active growth and development.

Interested candidates should forward their curriculum vitae to: Joel Rubenstein, M.D., Chairman, Search Committee, Newton-Wellesley Hospital, 2000 Washington Street, Newton, MA 02162.

NWH is an equal opportunity employer.

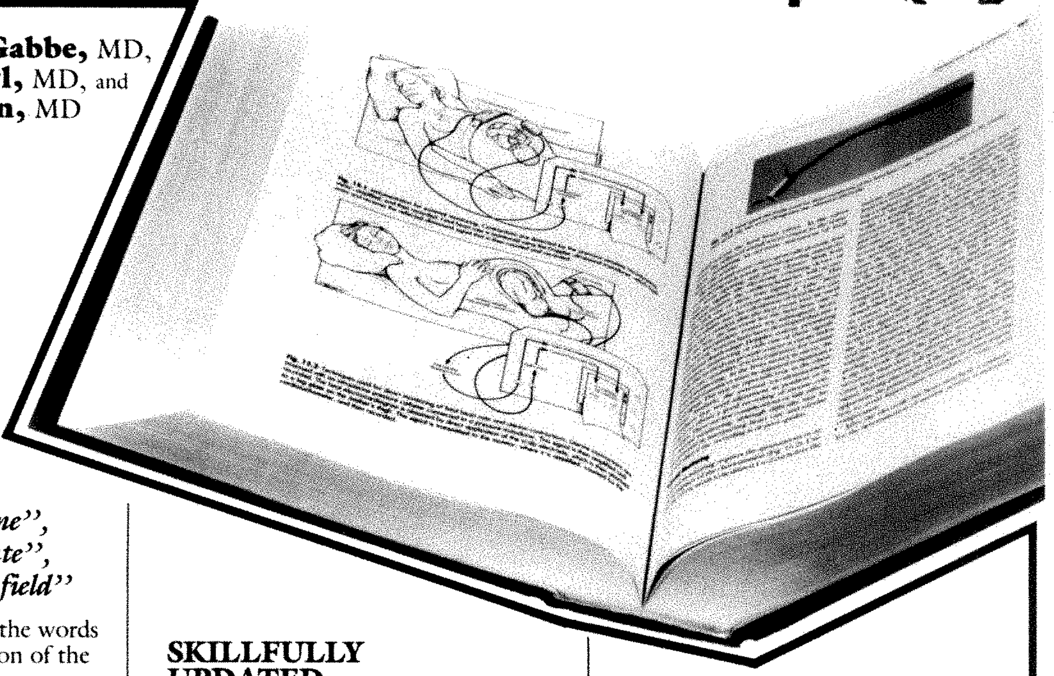
ANNOUNCING

the new
SECOND
EDITION of –

OBSTETRICS

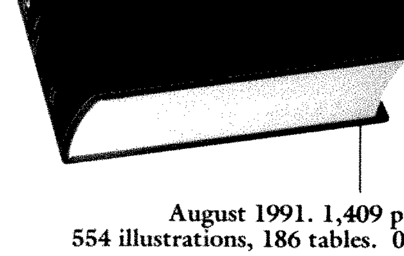
NORMAL AND PROBLEM PREGNANCIES

Edited by **Steven G. Gabbe,** MD,
Jennifer R. Niebyl, MD, and
Joe Leigh Simpson, MD
With 45 distinguished contributors
Illustrated by **Mickey Senkarik,** MS, AMI



"Excellent and innovative", "extraordinary depth", "a superb reference", "well written", "thorough and practical", "most welcome", "tremendous", "first rate", "edited by leaders in the field"

– These are just a few of the words ascribed to the First Edition of the most comprehensive reference on contemporary obstetric practice.



SKILLFULLY UPDATED AND REVISED

Now, following the precedent of excellence set by the First Edition, the same trio of editors once again collaborates with an outstanding roster of authors to carefully review and revise each chapter. To ensure inclusion of all state-of-the-art clinical information the new SECOND EDITION features:

- greatly expanded discussions on vital contemporary issues, including–ethical dilemmas resulting from new technologies, prenatal genetic diagnosis, acquired immune deficiency syndrome, prepregnancy counseling, and drugs of abuse
- new chapters on the increasingly important areas of ultrasound assessment of fetal anatomy and growth, and critical care in obstetrics
- a simpler, more convenient format designed to make various medical complications easier to locate
- over 200 new illustrations and photographs

To apply this wealth of information towards improving perinatal outcome, use the provided toll-free number and order your copy of **OBSTETRICS: Normal and Problem Pregnancies, Second Edition** today!

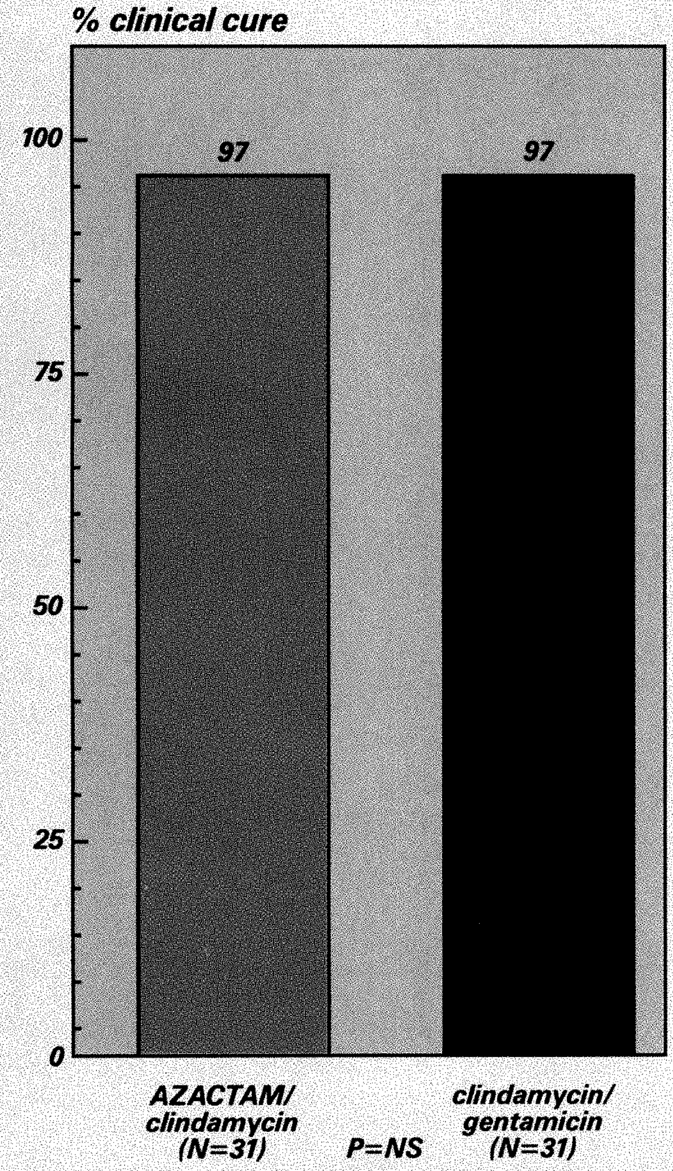
IN POSTPARTUM ENDOMETRITIS*



Azactam®

aztreonam

delivers...

A randomized, comparative trial of AZACTAM versus gentamicin, each with clindamycin, for the treatment of endometritis after delivery.[1]

No universal criteria exist that may satisfy a single definition of "cure." Use of this term may vary between clinical settings and investigators, and the reader is urged to consult the reference listed.

---

*Due to susceptible organisms.

†Although a useful guide, in vitro data do not necessarily correlate with therapeutic outcome.

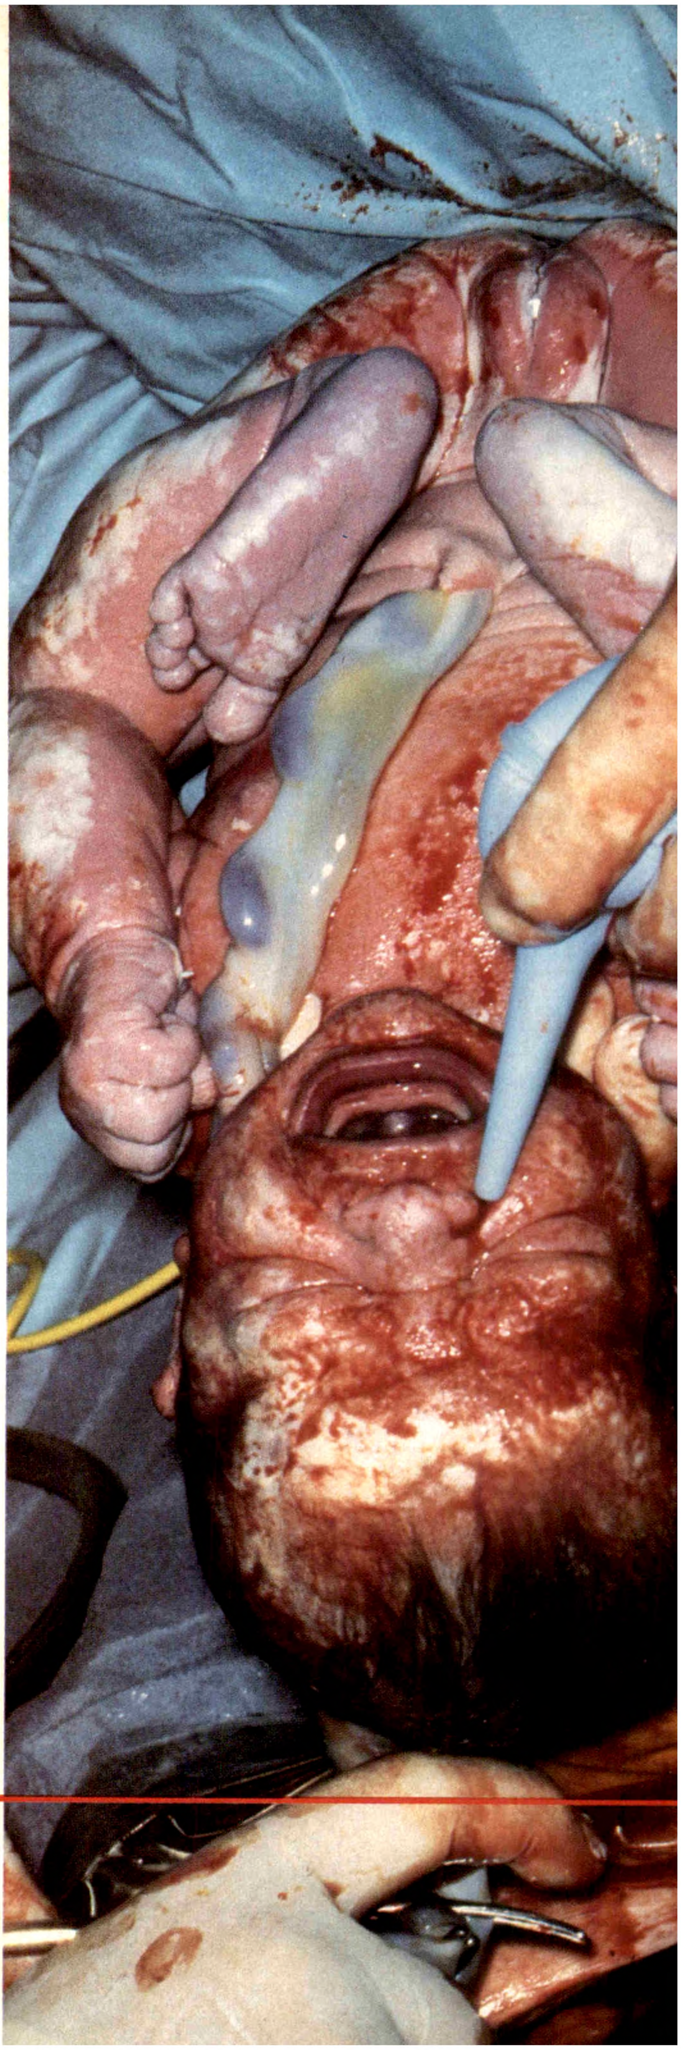
†Antibiotics should be given with caution to any patient who has had some form of allergy, particularly to drugs. See full prescribing information for recommendations on patients with immediate hypersensitivity reactions to penicillins.

Following IV administration, the most commonly seen adverse reactions occurred in less than 2% of patients, including local reactions, diarrhea, nausea/vomiting, and rash.

more than you're expecting...

- *Broad aerobic gram-negative in vitro coverage, including Escherichia coli, Proteus mirabilis, and Enterobacter cloacae.*[†]
- *Greater than 90% cure rates in combination with clindamycin.*[1-3]
- *No time-consuming, costly, routine therapeutic drug monitoring.*
- *May be admixed in the same bag with clindamycin.*
- *May be used in penicillin-allergic patients.*[‡]
- *Pregnancy Category B.*

There are no adequate and well-controlled studies in pregnant women. AZACTAM should be used in pregnant women only if clearly needed.



Azactam®

aztreonam

A logical alternative to aminoglycosides.

lease see adjacent page for brief summary of prescribing information.

Azactam®
aztreonam

AZACTAM® FOR INJECTION
Aztreonam For Injection

DESCRIPTION–AZACTAM (aztreonam, Squibb) is the first member of a new class of antibiotics classified as monobactams. AZACTAM is a totally synthetic bactericidal antibiotic with activity against a wide spectrum of gram-negative aerobic pathogens. The monobactams, having a unique monocyclic beta-lactam nucleus, are structurally different from other beta-lactam antibiotics.

AZACTAM For Injection is a sterile, nonpyrogenic, sodium-free, white to yellowish-white lyophilized cake, containing approximately 780 mg arginine per gram of aztreonam for intramuscular or intravenous use following constitution. Aqueous solutions of the product have a pH in the range of 4.5-7.5.

INDICATIONS AND USAGE–Before initiating treatment with AZACTAM, appropriate specimens should be obtained for isolation of the causative organism(s) and for determination of susceptibility to aztreonam. Treatment with AZACTAM may be started empirically before results of the susceptibility testing are available; subsequently, appropriate antibiotic therapy should be continued.

AZACTAM For Injection is indicated for the treatment of the following infections caused by susceptible gram-negative microorganisms: **Urinary Tract Infections** (complicated and uncomplicated), including pyelonephritis and cystitis (initial and recurrent) caused by *Escherichia coli, Klebsiella pneumoniae, Proteus mirabilis, Pseudomonas aeruginosa, Enterobacter cloacae, Klebsiella oxytoca*, Citrobacter* species* and *Serratia marcescens**. **Lower Respiratory Tract Infections,** including pneumonia and bronchitis caused by *Escherichia coli, Klebsiella pneumoniae, Pseudomonas aeruginosa, Haemophilus influenzae, Proteus mirabilis, Enterobacter* species and *Serratia marcescens**. **Septicemia** caused by *Escherichia coli, Klebsiella pneumoniae, Pseudomonas aeruginosa, Proteus mirabilis*, Serratia marcescens** and *Enterobacter* species. **Skin and Skin-Structure Infections,** including those associated with postoperative wounds, ulcers and burns caused by *Escherichia coli, Proteus mirabilis, Serratia marcescens, Enterobacter* species, *Pseudomonas aeruginosa, Klebsiella pneumoniae,* and *Citrobacter* species*. **Intra-abdominal Infections,** including peritonitis caused by *Escherichia coli, Klebsiella* species, including *K. pneumoniae, Enterobacter* species including *E. cloacae*, Pseudomonas aeruginosa, Citrobacter* species* including *C. freundii** and *Serratia* species* including *S. marcescens**. **Gynecologic Infections,** including endometritis and pelvic cellulitis caused by *Escherichia coli, Klebsiella pneumoniae*, Enterobacter* species* including *E. cloacae**, and *Proteus mirabilis**.

AZACTAM is indicated for adjunctive therapy to surgery in the management of infections caused by susceptible organisms, including abscesses, infections complicating hollow viscus perforations, cutaneous infections and infections of serous surfaces. AZACTAM is effective against most of the commonly encountered gram-negative aerobic pathogens seen in general surgery.

Concurrent Therapy–Concurrent initial therapy with other antimicrobial agents and AZACTAM is recommended before the causative organism(s) is known in seriously ill patients who are also at risk of having an infection due to gram-positive aerobic pathogens. If anaerobic organisms are also suspected, therapy should be initiated using an antianaerobic agent concurrently with AZACTAM. Certain antibiotics (e.g., cefoxitin, imipenem) may induce high levels of beta-lactamase *in vitro* in some gram-negative aerobes such as *Enterobacter* and *Pseudomonas* species, resulting in antagonism to many beta-lactam antibiotics including aztreonam. These *in vitro* findings suggest that such beta-lactamase inducing antibiotics not be used concurrently with aztreonam. Following identification and susceptibility testing, appropriate antibiotic therapy should be continued.

CONTRAINDICATIONS–Aztreonam is contraindicated in patients with known allergy to this antibiotic.

WARNINGS–Pseudomembranous colitis has been reported with nearly all antibacterial agents, including aztreonam, and may range in severity from mild to life-threatening. Therefore, it is important to consider this diagnosis in patients who present with diarrhea subsequent to the administration of antibacterial agents.

Treatment with antibacterial agents alters the normal flora of the colon and may permit overgrowth of clostridia. Studies indicate that a toxin produced by *Clostridium difficile* is one primary cause of "antibiotic-associated colitis."

After the diagnosis of pseudomembranous colitis has been established, therapeutic measures should be initiated. Mild cases of pseudomembranous colitis usually respond to drug discontinuation alone. In moderate to severe cases, consideration should be given to management with fluids and electrolytes, protein supplementation, and treatment with an oral antibacterial drug effective against *C. difficile* (e.g., vancomycin). Careful inquiry should be made for a history of hypersensitivity reaction to any antibiotic or other drugs. Antibiotics should be given with caution to any patient who has had some form of allergy, particularly to drugs. It is recommended that patients who have had immediate hypersensitivity reactions (e.g., anaphylactic or urticarial) to penicillins and/or cephalosporins should be followed with special care. If an allergic reaction to aztreonam occurs, discontinue the drug and institute supportive treatment as appropriate (e.g., maintenance of ventilation, pressor amines, antihistamines, corticosteroids). Serious hypersensitivity reactions may require epinephrine and other emergency measures.

PRECAUTIONS–General: In patients with impaired hepatic or renal function, appropriate monitoring is recommended during therapy. If an aminoglycoside is used concurrently with aztreonam, especially if high dosages of the former are used or if therapy is prolonged, renal function should be monitored because of the potential nephrotoxicity and ototoxicity of aminoglycoside antibiotics. The use of antibiotics may promote the overgrowth of nonsusceptible organisms, including gram-positive organisms and fungi. Should superinfection occur during therapy, appropriate measures should be taken.

Carcinogenesis, Mutagenesis, Impairment of Fertility–Carcinogenicity studies in animals have not been performed. Genetic toxicology studies performed *in vivo* and *in vitro* with aztreonam in several standard laboratory models revealed no evidence of mutagenic potential at the chromosomal or gene level. Two-generation reproduction studies in rats at daily doses up to 20 times the maximum recommended human dose, prior to and during gestation and lactation, revealed no evidence of impaired fertility. There was a slightly reduced survival rate during the lactation period in the offspring of rats that received the highest dosage, but not in offspring of rats that received five times the maximum recommended human dose.

Pregnancy–Pregnancy Category B: Aztreonam crosses the placenta and enters the fetal circulation. Studies in pregnant rats and rabbits, with daily doses up to 15 and 5 times, respectively, the maximum recommended human dose, revealed no evidence of embryo- or fetotoxicity or teratogenicity. No drug induced changes were seen in any of the maternal, fetal or neonatal parameters that were monitored in rats receiving 15 times the maximum recommended human dose of aztreonam during late gestation and lactation. There are no adequate and well-controlled studies in pregnant women. Because animal reproduction studies are not always predictive of human response, aztreonam should be used during pregnancy only if clearly needed.

Nursing Mothers–Aztreonam is excreted in breast milk in concentrations that are less than 1% of concentrations determined in simultaneously obtained maternal serum; consideration should be given to temporary discontinuation of nursing and use of formula feedings.

Pediatric Use–Safety and effectiveness have not been established in infants and children.

ADVERSE REACTIONS–Local reactions such as phlebitis/thrombophlebitis following IV administration, and discomfort/swelling at the injection site following IM administration occurred at rates of approximately 1.9% and 2.4%, respectively. Systemic reactions (considered to be related to therapy or of uncertain etiology) occurring at an incidence of 1 to 1.3% include diarrhea, nausea and/or vomiting, and rash. Reactions occurring at an incidence of less than 1% are listed within each body system in order of decreasing severity; *Hypersensitivity*–anaphylaxis. *Hematologic*–pancytopenia, neutropenia, thrombocytopenia, anemia, leukocytosis, thrombocytosis. *Gastrointestinal*–abdominal cramps; rare cases of *C. difficile*-associated diarrhea, including pseudomembranous colitis, or gastrointestinal bleeding have been reported. Onset of pseudomembranous colitis symptoms may occur during or after antibiotic treatment (see WARNINGS). *Dermatologic*–purpura, erythema multiforme, urticaria, exfoliative dermatitis, petechiae, pruritus, diaphoresis. *Cardiovascular*–hypotension, transient ECG changes (ventricular bigeminy and PVC). *Respiratory*–one patient experienced flushing, chest pain, and dyspnea. *Hepatobiliary*–hepatitis, jaundice. *Nervous System*–seizure, confusion, vertigo, paresthesia, insomnia, dizziness. *Musculoskeletal*–muscular aches. *Special Senses*–tinnitus, diplopia, mouth ulcer, altered taste, numb tongue, sneezing and nasal congestion, halitosis. *Other*–vaginal candidiasis, vaginitis, breast tenderness. *Body as a Whole*–weakness, headache, fever, malaise.

Adverse Laboratory Changes–Those reported without regard to drug relationship during clinical trials were: *Hepatic*–elevations of AST (SGOT), ALT (SGPT), and alkaline phosphatase; signs or symptoms of hepatobiliary dysfunction occurred in less than 1% of recipients (see above). *Hemic*–increases in prothrombin and partial thromboplastin times, eosinophilia, positive Coombs test. *Renal*–increases in serum creatinine.

OVERDOSAGE–If necessary, aztreonam may be cleared from the serum by hemodialysis and/or peritoneal dialysis.

DOSAGE AND ADMINISTRATION–Dosage adjustments are recommended for patients with impaired renal function. In elderly patients, estimates of creatinine clearance should be obtained and appropriate dosage modifications made if necessary.

HOW SUPPLIED–AZACTAM For Injection (Aztreonam For Injection)–Lyophilized–is supplied in single-dose 15 mL vials containing **500 mg,** or **1 g**/vial; in single-dose 30 mL vials containing **2 g**/vial; and in single-dose 100 mL intravenous infusion bottles containing **500 mg** or **1 g** or **2 g**/bottle.

Consult package insert before prescribing AZACTAM (aztreonam). (J4-231C)

Hypoplastic left heart syndrome: Prenatal diagnosis, clinical profile, and management

Danielle M. Blake, MD, Joshua A. Copel, MD, and Charles S. Kleinman, MD
New Haven, Connecticut

We diagnosed hypoplastic left heart syndrome, generally regarded as a lethal congenital heart defect, by fetal echocardiography in 20 pregnancies in the last 5 years. The clinical profile, management, and outcome of these pregnancies were reviewed. We found a 40% association of karyotype and extracardiac malformations. Elective abortion was performed in nine pregnancies. Two of seven live-born babies had early neonatal assessment and intervention as a result of in utero diagnosis and counseling. Prolonged survival was achieved in both infants. We conclude that prenatal diagnosis of the hypoplastic left heart syndrome necessitates complete evaluation of the fetus for associated genetic and extracardiac malformations. Prenatal diagnosis of this defect provides opportunities for in depth counseling of parents and obtaining informed consent for either postnatal intervention or nonintervention before the medical and emotional complexities associated with the neonatal intensive care setting are encountered. (AM J OBSTET GYNECOL 1991;165:529-34.)

Key words: Hypoplastic left heart syndrome, prenatal diagnosis, congenital heart disease

Hypoplastic left heart syndrome is a congenital heart defect that ranges in severity from critical aortic stenosis with nearly normal left ventricular and mitral valve dimensions to the most severe form in which both aortic and mitral valves are atretic and the left ventricle is absent or extremely underdeveloped.[1] It is the most common cause of death from heart disease during the first week of life. The greatest risk of dying occurs on day 3, at the time of ductal closure.[2,3] If left untreated, it is a lethal cardiac malformation.[4]

The prenatal diagnosis of hypoplastic left heart syndrome by fetal echocardiography has recently been well documented.[5-7] The ability to diagnose this and other structural heart defects in utero is a major contribution of high-resolution ultrasonography to obstetric care. The antenatal diagnosis of hypoplastic left heart syndrome mandates counseling of the parents; it affects further evaluation and management plans during the remainder of the pregnancy and during postnatal care of the neonate. Although the in utero diagnosis of hypoplastic left heart syndrome has been reported and management of the neonate with this defect is well described,[2,4] a comprehensive review of the clinical profile, management, and outcome of pregnancies diagnosed prenatally is lacking. In this article we present our center's 5-year experience with the prenatal diagnosis of hypoplastic left heart and review the characteristics, management, and outcome of the affected pregnancies.

Material and methods

All fetal echocardiograms obtained in the Fetal Cardiovascular Center at Yale University School of Medicine between January 1986 and December 1990 were reviewed. Indications for referral were factors known to be associated with increased risk for congenital heart disease in the fetus (Table I). At the time of study all patients underwent a detailed ultrasonographic examination followed by fetal echocardiography with 3.5 or 5.0 MHz transducers (model 77020AC, Hewlett-Packard, Andover, Mass.; Ultramark 9, Advanced Technology Laboratories, Bothell, Wash.).

Fetal echocardiograms included two-dimensional views of the four chambers, long- and short-axis views of the ventricular outflow tracts and great arteries, and aortic and ductal arch views. Two-dimensional real-time examination was supplemented by pulsed and color flow Doppler as these systems became available.

Pregnancies complicated by the prenatal diagnosis of hypoplastic left heart syndrome composed the study population. Scans were performed by a physician experienced in fetal cardiac ultrasonography and recorded on videotape for future review. Follow-up information was obtained from clinical or autopsy records from Yale–New Haven Hospital or by contacting the referring physicians. Parents were advised of the echocardiographic findings at the time of diagnosis. Management options for the pregnancy and postnatal period were explained. These included continuation of the pregnancy with either neonatal cardiac

transplantation[8] or performance of a Norwood procedure[9] or nonintervention with compassionate care of the baby after birth.[10] Patients were informed that termination of pregnancy was an option at <24 weeks' gestation.

The indication for the study, the gestational age at diagnosis, associated extracardiac abnormalities, and fetal karyotype were reviewed. Pregnancy outcome was categorized as elective abortion or continuation of pregnancy resulting in either an intrauterine fetal death or a live-born infant. Pregnancies that continued to viability had the neonatal course reviewed with regard to intervention or nonintervention and survival. Autopsy records were reviewed where available.

Results

Between 1986 and 1990 we diagnosed hypoplastic left heart syndrome in 20 fetuses. The most common indication for referral for fetal echocardiography among this group of patients was an abnormal four-chamber view on general obstetric ultrasonographic examination (Tables II and III).

The diagnosis of hypoplastic left heart syndrome was made by the observation of a diminutive left ventricle and left atrium on the four-chamber view, with an enlarged right ventricle and right atrium. Mitral and aortic valve leaflet motion was absent or minimal. An abnormally narrowed aortic root and ascending aorta seen on the long axis great vessel view bordered by an enlarged pulmonary artery also suggested the diagnosis.

Color flow Doppler was helpful in establishing the diagnosis of hypoplastic left heart syndrome in 10 of the 15 cases in which it was used. Lack of blood flow into the left ventricle consistent with mitral valve atresia was seen in five cases (6, 7, 9, 16, and 20). Four cases (1, 2, 14, and 17) were associated with abnormal flow at the foramen ovale, with shunting from the left to the right atrium. At the site of entry into the descending aorta blood flow from the ductus arteriosus was observed to branch, flowing forward into the descending aorta and retrograde into the ascending aorta in five cases (1, 6, 16, 17, and 20). Forward flow into the ascending aorta was visualized in two cases (11 and 14). In 15 cases classic hypoplastic left heart syndrome, with mitral and aortic atresia, was diagnosed prenatally. A variant of this syndrome was diagnosed in an additional five cases (7, 8, 11, 14, and 18).

Fourteen patients had the diagnosis made before viability (Table II). Associated extracardiac abnormalities were identified prenatally in six fetuses. Four fetuses had cystic hygromas with associated nonimmune hydrops in three. The remaining abnormalities included a two-vessel cord and a cleft palate. Abnormal karyotypes were found in three fetuses. The karyotype abnormalities were 45,X in two fetuses with cystic hygromas and nonimmune hydrops and trisomy 13 in the fetus with cleft palate. Elective termination of pregnancy was performed in nine of the pregnancies diagnosed before viability. The remaining five patients decided to continue pregnancy. Three of these pregnancies resulted in intrauterine fetal death. One death occurred in a twin gestation with one affected fetus and a normal cotwin. The affected twin had trisomy 13 syndrome and a posterior cleft palate on ultrasonography; this twin died at 26 weeks' gestation. The other intrauterine deaths occurred at 22 weeks 5 days and at 24 weeks in two singleton pregnancies, one with isolated hypoplastic left heart syndrome and the other with cystic hygroma and a 45,X karyotype, respectively. Viable newborns were delivered at term in the remaining two pregnancies. Neither had any postnatal surgical intervention. The ages at death were 2 and 8 days. In 10 of these 14 cases either autopsy or postnatal echocardiography was done after completion of the pregnancy. In nine of these 10 cases further evaluation confirmed the prenatal diagnosis of hypoplastic left heart syndrome. The fetal heart in case 13 was grossly hypoplastic at autopsy, weighing only 0.9 gm. Chamber size and other structural dimensions could not be obtained because of the extremely small size of the heart. Follow-up studies were not done in cases 1, 7, 9, and 10.

Six patients had cardiac diagnosis made after 24 weeks (Table III). None of these six fetuses had an abnormal karyotype. Extracardiac abnormalities were present in two fetuses. One fetus had a two-vessel cord, and the other had an omphalocele. There was a single intrauterine death at 30 weeks' gestation. Expectant management and compassionate care had been decided on after the prenatal diagnosis of hypoplastic left heart syndrome had been made. However, cesarean delivery was performed in the setting of preterm labor and malpresentation. Autopsy confirmed mitral-aortic atresia with left ventricular hypoplasia. The only twin gestation in this group involved an affected fetus and a normal

20	29	Low MSAFP Abnormal four chambers	—	46,XX	Live-born; died on day 2

CHD, Congenital heart defect; *MSAFP*, maternal serum α-fetoprotein.

cotwin (case 16). Digoxin was administered to the mother with subsequent improvement in fetal hydrops and polyhydramnios in the affected twin, which had contributed to preterm labor. A noninterventional approach had been planned for the affected twin. Postnatal echocardiography after a term delivery confirmed the prenatal diagnosis. Neonatal death occurred on day 5.

Live-born infants were delivered in the remaining four pregnancies. Two of these babies had early postnatal intervention after confirmatory neonatal echocardiograms. In case 15 the infant underwent a Norwood procedure and currently is alive, having achieved appropriate developmental milestones at 2½ years. In case 18 the fetus was diagnosed prenatally as having a variant of hypoplastic left heart syndrome and postnatally underwent multiple cardiac surgical procedures on day 1, at 4 months, and at 18 months with ultimate death of the infant at 2½ years of intractable congestive heart failure. The remaining two live-born infants died on the first day of life. In case 19 the infant died within minutes of birth and had neither postnatal echocardiography nor autopsy. Case 20 had the cardiac diagnosis confirmed by postnatal echocardiographic study before death of the infant on day 2.

Overall, the outcomes of these 20 pregnancies included nine elective abortions, four intrauterine deaths, and seven live births. Neonatal death occurred between days 1 and 8 in five babies. Prolonged survival was achieved in two newborns who underwent early surgical intervention. The sole survivor at this time is a 2½-year-old child who underwent a Norwood procedure.

Comment

This series of cases demonstrates a poor outcome for the majority of pregnancies with the in utero diagnosis of hypoplastic left heart syndrome. A similar poor prognosis for pregnancies with prenatal diagnosis of a variety of congenital heart defects was described by Crawford et al.,[11] who reported only 17% survival of offspring of continuing pregnancies. Associated extracardiac or chromosomal anomalies occurred in 46% of cases with cardiac defects diagnosed prenatally. In this series of cases there were nine perinatal deaths among 11 continuing pregnancies. The two cases of prolonged survival both were subsequent to postnatal surgery. If elective abortions are included, the mortality figure is increased (18 of 20 pregnancies). Forty percent of cases diagnosed prenatally in our series had associated extracardiac or karyotype abnormalities. This is consistent with the data reported by Crawford et al. for prenatally diagnosed heart defects in general; however, it is considerably increased above the 28% frequency of genetic and major extracardiac abnormalities associated with hypoplastic left heart syndrome reported by Natowicz et al.[12] from pediatric autopsy cases and the 11% association reported by Morris.[5]

Series with prenatal diagnosis include cases of extracardiac abnormalities that underwent elective abortions and intrauterine deaths that may not be included in pediatric statistics and so explain the apparent discrepancy. Consistent with neonatal data,[13] the presence of Turner's syndrome in newborns with left-sided heart disease was cytogenetically confirmed in two of the four cases with in utero diagnosis of hypoplastic left heart syndrome and cystic hygromas. All three abnormal karyotypes were found in previable fetuses, two of which died in utero. No fetus with a diagnosis made after 24 weeks had an abnormal karyotype. Three of five continuing pregnancies diagnosed at <24 weeks had intrauterine deaths, compared to one of six pregnancies with a diagnosis made after 24 weeks. Our observations are consistent with poor in utero survival of cytogenetically abnormal fetuses with a diagnosis made early in pregnancy.[14] Abnormal cytogenetic studies may alter counseling regarding recurrence risks for future pregnancies, should features suggestive of a genetic syndrome be identified. Karyotype abnormalities and severe extracardiac malformations also may alter candidacy for postnatal surgery. These data are consistent with our previous suggestion that complete prenatal evaluation includes cytogenetic study of a pregnancy with a diagnosis of hypoplastic left heart syndrome.[15]

Prenatal diagnosis of hypoplastic left heart syndrome affords the opportunity for early intervention in the postnatal course of the neonate. Hypoplastic left heart syndrome renders the neonate dependent on persistent ductal patency to provide systemic blood flow; therefore prenatal diagnosis of hypoplastic left heart syndrome allows early postnatal confirmation of the diagnosis, with subsequent administration of prostaglandin E_1 infusion to maintain ductal patency before significant deterioration of the neonate. In addition, timely institution of ventilatory support can be initiated.[2, 4] If cardiac transplantation is planned, additional time is gained to find a donor and to relocate the family to the appropriate facility for delivery and surgery.[8, 16] In this review two patients underwent postnatal intervention. Both deliveries occurred at the institutions chosen for postnatal surgery. Prolonged survival was achieved as a result of early surgery preceded by prostaglandin infusion and monitoring of the newborn.

Prolonged emotional distress has been cited as a potential disadvantage of providing the parents with the prenatal diagnosis of hypoplastic left heart syndrome.[16] However, Veille et al.[10] suggested that full disclosure of all information obtained from prenatal studies along with prognosis and treatment options is of paramount importance in decision-making for couples with this in utero diagnosis. In addition, we believe that in utero diagnosis of this defect is ultimately beneficial to the parents. The process of obtaining truly informed consent for either postnatal treatment or nontreatment is clearly facilitated when the diagnosis is made antenatally, when there are multiple opportunities for continued discussions with care givers. The couple gains time and perspective and is able to start coping with their initial feelings of grief and denial. Decisions regarding postnatal management will then be made in a more appropriately thoughtful manner, rather than during the unexpected emotional turmoil brought on by an unexpected neonatal diagnosis. All patients in our series were counseled regarding the prognosis of infants with hypoplastic left heart syndrome at the time of prenatal diagnosis. Postnatal modes of treatment were explained, as was the option of nontreatment. Discussion of elective abortion was offered as a legal option for previable pregnancies.

The risk of misdiagnosis is certainly a potential disadvantage, as has been cited by Johnston and Sakala.[16] Fetal echocardiography has been shown to be accurate in defining fetal cardiac anatomy[17] and in the detection of congenital heart defects.[18, 19] In addition, recent advances in ultrasonographic technology have provided systems that facilitate correct in utero diagnosis of congenital heart defects. Pulsed Doppler is accepted as an important adjunct to two-dimensional fetal echocardiography, and the use of this technology to diagnose hypoplastic left heart syndrome prenatally has been reported.[20, 21] Color flow mapping facilitates identification of small cardiac and vascular structures, allowing real-time visualization of direction of blood flow in cardiac structures and great vessels.[22, 23] Chiba et al.[24] suggested that in their hands color flow mapping increased the sensitivity of fetal echocardiography to correctly diagnose fetal structural heart disease above that of conventional two-dimensional imaging (from 58% to 76%), although we have not found color flow to improve the sensitivity of structural diagnosis in our laboratory.[25] The use of this technique to diagnose hypoplastic left heart syndrome has been reported.[23-27] We found color flow Doppler to be helpful in diagnosing hypoplastic left heart syndrome in 10 of the 15 cases in which it was used. This technology combined with experience in fetal echocardiography minimizes the risk of misdiagnosis. We have not documented false-positive diagnoses of hypoplastic left heart syndrome and believe that if a skilled observer performs these studies such misdiagnosis should be virtually impossible.

The use of the four-chamber view as a sensitive screen for intracardiac malformations has been documented.[28] Fourteen of the 20 cases presented had fetal echocardiography because of an abnormal four-chamber view. We anticipate that as the use of this screening tool increases the prenatal diagnosis of congenital heart defects will improve.

In conclusion, we have reported a series of pregnancies with hypoplastic left heart syndrome diagnosed in utero by conventional fetal echocardiography supplemented by pulsed and color flow Doppler. These pregnancies exhibited poor perinatal survival in part because of associated genetic and structural abnormalities that resulted in elevated intrauterine and neonatal mortality. Prolonged survival was achieved in two cases with prenatal diagnosis and counseling and afforded the opportunity of early neonatal intervention. Neonatal management of these infants is evolving. Although the Norwood procedure[9] and neonatal transplantation[8] are innovative techniques, there are few long-term clinical data currently available. The neonatal counseling for these families is therefore complex. We have found that by obtaining diagnostic information prenatally we have been able to afford this population an opportunity to make more informed decisions than had they been compelled to decide under the pressure of the neonatal intensive care setting. It is anticipated that fetal echocardiography will continue to be an accurate tool for the in utero diagnosis of severe congenital heart defects and will contribute to the management of pregnancies so complicated and to preparations for neonatal surgical intervention.

Bound volumes available to subscribers

Bound volumes of the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY are available to subscribers (only) for the 1991 issues from the Publisher, at a cost of $61.00 for domestic, $88.27 for Canada, and $84.00 for international for Vol. 164 (January-June) and Vol. 165 (July-December). Shipping charges are included. Each bound volume contains a subject and author index and all advertising is removed. Copies are shipped within 60 days after publication of the last issue in the volume. The binding is durable buckram with the JOURNAL name, volume number, and year stamped in gold on the spine. *Payment must accompany all orders.* Contact Mosby–Year Book, Inc., Subscription Services, 11830 Westline Industrial Drive, St. Louis, MO 63146-3318, USA; phone (800) 325-4177, ext. 4351.

Subscriptions must be in force to qualify. Bound volumes are not available in place of a regular JOURNAL subscription.

Adrenal and ovarian steroid hormone responses to gonadotropin-releasing hormone agonist treatment in polycystic ovary syndrome

Frank Gonzalez, MD, Denise A. Hatala, BS, and Leon Speroff, MD
Cleveland, Ohio

It has been postulated that in polycystic ovary syndrome ovarian steroids can influence adrenal steroidogenesis. To test this hypothesis, basal and dexamethasone-suppressed–corticotropin-stimulated steroid hormone responses were compared among three groups of women before, during, and after gonadotropin-releasing hormone agonist treatment for 3 months. The groups were characterized as follows: (1) women with polycystic ovary syndrome with high dehydroepiandrosterone sulfate levels (>400 μg/dl), (2) women with polycystic ovary syndrome with normal dehydroepiandrosterone sulfate levels (<300 μg/dl), and (3) normal ovulatory women. In response to gonadotropin-releasing hormone agonist, basal serum luteinizing hormone, follicle-stimulating hormone, estradiol, estrone, 17-hydroxyprogesterone, androstenedione, and testosterone in all three groups were suppressed to similar levels. Basal serum dehydroepiandrosterone sulfate levels in the group with high levels declined, but they did not reach the normal, unaltered concentrations in the other two groups. Two subjects with polycystic ovary syndrome in this group with high levels, who showed the greatest declines in basal serum dehydroepiandrosterone sulfate levels (34%, 40%), also had evidence of 3β-hydroxysteroid dehydrogenase deficiency before treatment, which was resolved by the end of treatment. In both groups with polycystic ovary syndrome, the increase in maximum incremental rise of dehydroepiandrosterone and dehydroepiandrosterone sulfate levels in response to a pharmacologic dose of corticotropin from a dexamethasone-suppressed baseline (adrenal androgen capacity) remained unaltered during gonadotropin-releasing hormone agonist administration. We conclude that ovarian steroids may promote excessive adrenal androgen secretion in women with polycystic ovary syndrome, may induce 3β-hydroxysteroid dehydrogenase deficiency as a mechanism for adrenal involvement in some women with polycystic ovary syndrome, and do not influence adrenal androgen capacity. (AM J OBSTET GYNECOL 1991;165:535-45.)

Key words: Polycystic ovary syndrome, gonadotropin-releasing hormone agonist, dehydroepiandrosterone sulfate, 3β-hydroxysteroid dehydrogenase deficiency

The mechanism of excess adrenal androgen secretion in polycystic ovary syndrome remains controversial. It has been postulated that ovarian steroids influence adrenal steroidogenesis by inhibition of adrenal 3β-hydroxysteroid dehydrogenase activity or by causing adrenal androgen hyperresponsiveness to corticotropin. This hypothesis may account for the elevations in serum levels of dehydroepiandrosterone sulfate (DHA-S) observed in approximately half of women with polycystic ovary syndrome.[1,2] Administration of a long-acting gonadotropin-releasing hormone (GnRH) agonist has been reported to selectively suppress pituitary gonadotropins and secretion of ovarian steroids in women with polycystic ovary syndrome.[3,4] However, the effect of administering GnRH agonist to women with polycystic ovary syndrome with high DHA-S levels (>400 μg/dl) has never been examined. Thus this study was undertaken to determine if women with polycystic ovary syndrome and high DHA-S levels have a different adrenal response than do women with polycystic ovary syndrome and normal DHA-S levels to GnRH agonist administration for 3 months. Basal and dexamethasone-suppressed–corticotropin-stimulated hormone profiles were evaluated before, during, and after treatment, and the results were compared with those in a group of normal ovulatory women who were similarly evaluated for the same period of time.

Material and methods

Subjects. Ten women with polycystic ovary syndrome were selected for study because they showed elevation in at least one serum androgen level (DHA-S, >340

μg/dl; total testosterone, >0.7 ng/ml, or free testosterone, >0.8 ng/ml) and exhibited the classic features of oligomenorrhea and hirsutism. All had normal prolactin levels (<20 μg/L), were euthyroid (thyroid-stimulating hormone, <3.5 mIU/L), and had a positive response to medroxyprogesterone withdrawal. The clinical characteristics of these women are shown in Table I. All were between 18 and 35 years of age, nine were obese (>120% of ideal body weight), and one had acanthosis nigricans. Although all subjects with polycystic ovary syndrome underwent vaginal ultrasonography for ovarian characterization before the study, enlarged or polycystic ovaries were not required for the diagnosis of polycystic ovary syndrome. In retrospect, all exhibited low-dose dexamethasone suppression of cortisol to <5 μg/dl, as well as basal serum and postcorticotropin 17-hydroxyprogesterone levels that were <3 ng/ml at the beginning of the study to exclude Cushing's disease and attenuated 21-hydroxylase deficiency, respectively.

Three groups of subjects were studied, after institutional review board approval and informed consent. Basal serum DHA-S levels drawn at the beginning of the study were used to assign half (n = 5) of the subjects with polycystic ovary syndrome to the high DHA-S group (>400 μg/dl) and the remaining half to the normal DHA-S group (<300 μg/dl). The third group consisted of five normal ovulatory women similar in age to the subjects with polycystic ovary syndrome. All had regular menses and no evidence of hirsutism. All demonstrated a biphasic basal body temperature curve and a luteal range serum progesterone level (>6 ng/ml) after the temperature shift, in the cycle before the study was begun. None of the subjects in any group had received hormonal medication for at least 6 weeks before the study.

Protocol. All three groups received a GnRH agonist (leuprolide acetate, TAP Pharmaceuticals, North Chicago; 2 mg self-injected subcutaneously daily at 8 AM) for 3 months. The injections in subjects with polycystic ovary syndrome were begun without regard to the patient's previous menstrual period and in ovulatory women during the mid to late follicular phase of the menstrual cycle.

Each subject underwent a baseline evaluation of basal secretion and adrenal dynamic response during the week before GnRH agonist treatment was started. Blood samples were collected at 8 AM every 3 days (−8, −5, and −2 days) for calculation of the mean to represent basal secretion. On the evening of the final basal blood drawing, study subjects were admitted to the General Clinical Research Center of University Hospitals of Cleveland. Dexamethasone (1 mg orally) was given at 11 PM followed by an intravenous bolus of 0.25 mg synthetic corticotropin (1-24) (Cortrosyn, Organon, West Orange, N.J.) at 8 AM the next morning. Blood samples were collected through an indwelling catheter at −15, 0, 60, and 180 minutes after corticotropin injection. During GnRH agonist administration, blood samples were drawn at monthly intervals at 8 AM just before the daily injection of the medication. Adrenal dynamic testing was repeated after the first month and at the end of treatment, but on these occasions, the GnRH agonist injection was given at 7:30 AM, 30 minutes before the corticotropin injection.

The serum levels used for screening patients were measured in the General Chemistry Laboratory of University Hospitals of Cleveland from blood samples drawn within 6 months before the study in women with polycystic ovary syndrome and during the cycle before the study in ovulatory women. Screening levels of DHA-S, total testosterone, and progesterone were mea-

sured with radioimmunoassay kits obtained from Pantex Corp. (Santa Monica, Calif.), while those for prolactin and thyroid-stimulating hormone were measured with radioimmunoassay kits obtained from DELFIA, Pharmacia ENI, Inc. (Fairfield, N.J.). Screening levels of free testosterone were measured by a method described previously.[5] Actual study data were generated by measuring serum luteinizing hormone (LH), follicle-stimulating hormone (FSH), estradiol, androstenedione, testosterone, 17-hydroxyprogesterone, dehydroepiandrosterone (DHA), DHA-S, and cortisol with radioimmunoassay kits obtained from Diagnostic Products Corp. (Los Angeles) or by Nichols Institute (San Juan Capistrano, Calif.), where serum estrone and 17-hydroxypregnenolone were measured. For a given hormone all samples from an individual patient were measured in duplicate in the same assay. The intraassay and interassay coefficients of variation were below 9% and 12.3%, respectively, for all assays, except those for the 17-hydroxypregnenolone assay, which were 9.3% and 15.5%, respectively.

The adrenal response after corticotropin injection during baseline dynamic testing (0 months) was used to determine adrenal enzyme activities, adrenal androgen capacity, and cortisol output. The mean ratios of the maximum absolute values of the appropriate substrates to products in the high and normal DHA-S groups were compared with those in ovulatory women to detect differences in the activities of 3β-hydroxysteroid dehydrogenase and 17,20-lyase in either group with polycystic ovary syndrome. With criteria similar to those described previously,[6] women with polycystic ovary syndrome in whom the maximum absolute values of DHA or 17-hydroxypregnenolone and the ratios of the maximum absolute values of DHA to androstenedione and 17-hydroxypregnenolone to cortisol were >2 SD above the mean of ovulatory women were considered to have 3β-hydroxysteroid dehydrogenase deficiency. Ratios of the maximum absolute values of 17-hydroxypregnenolone to DHA or 17-hydroxyprogesterone to androstenedione that were >2 SD below the mean of normal ovulatory women were required to fulfill the criteria for 17,20-lyase hyperactivity. Cortisol output was defined as the maximum absolute value of cortisol secreted. The maximum incremental rise in DHA and DHA-S secretion from a standardized dexamethasone-suppressed baseline (mean of values at −15 and 0 minutes) was calculated to represent adrenal androgen capacity. Alterations in these parameters during GnRH agonist administration were determined from adrenal dynamic testing performed after 1 month and 3 months of treatment.

Statistical evaluation was performed with two-way analysis of variance, followed by Student paired or group *t* tests, where appropriate. One-tailed significance was considered sufficient when paired comparisons were assessed for the basal serum levels of LH, FSH, estradiol, estrone, 17-hydroxyprogesterone, androstenedione, and testosterone because only declines in these hormones were anticipated in response to GnRH agonist, as demonstrated previously.[3,4,7,8] However, two-tailed significance was used for all other comparisons. The Bonferroni test was chosen to control for multiple comparisons when differences across groups during treatment were assessed.[9] In this instance a value of 0.017 was used to detect a significant difference at the level of 0.05. Linear regression was used to examine correlations in the responses to GnRH agonist among the basal serum levels of estradiol, estrone, and DHA-S.

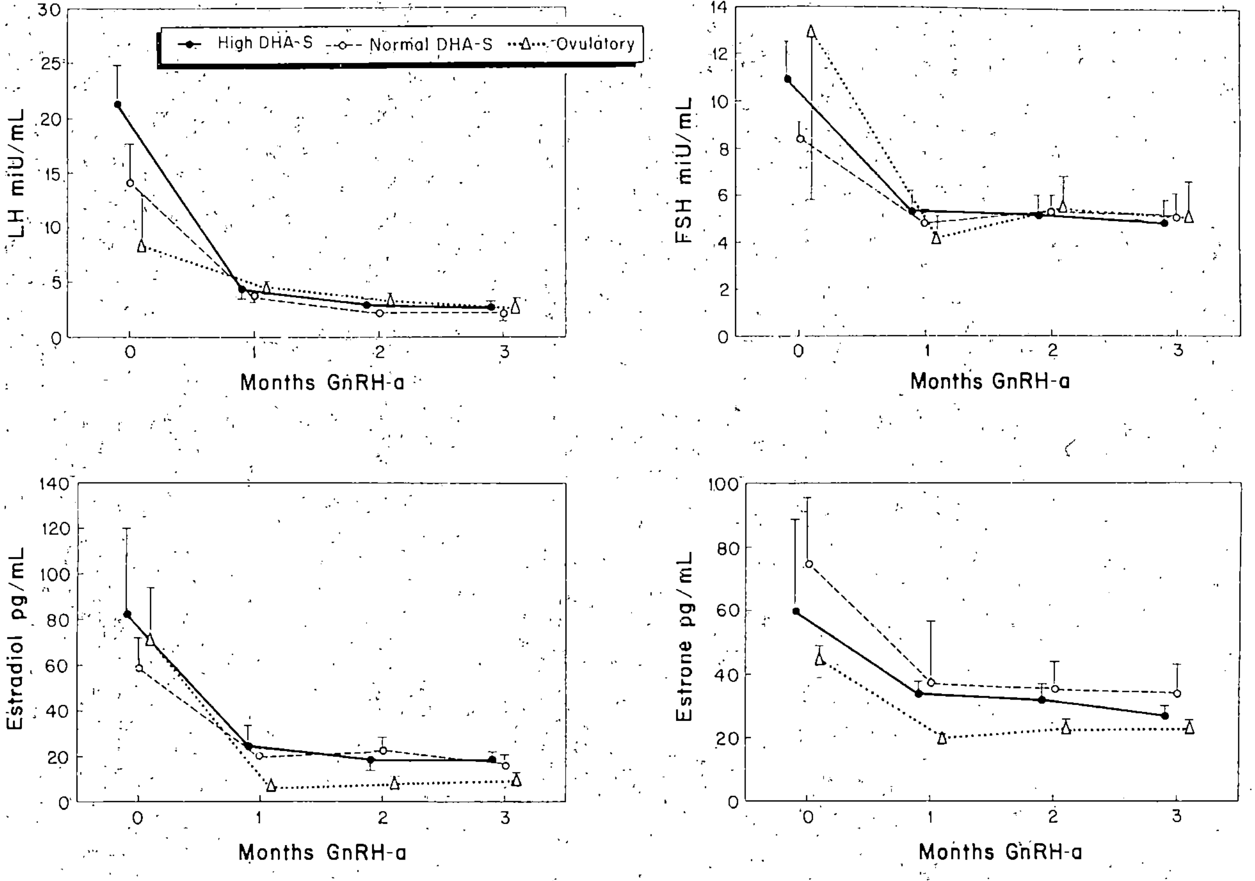

Fig. 1. Basal serum LH, FSH, estradiol, and estrone concentrations (mean ± SE) in women with polycystic ovary syndrome with high and normal DHA-S levels and in ovulatory women before and during GnRH agonist *(GnRH-a)* treatment. Factors used to convert data into Systèm International d'Unités (SI units) are 3.671 and 3.699 for estradiol and estrone, respectively.

Results

Basal hormonal response

Baseline hormone concentrations. The baseline hormonal characteristics of the three treatment groups are shown in Table II. The mean serum concentrations of androstenedione, testosterone, DHA, and DHA-S just before treatment were significantly higher ($p < 0.05$) in the high DHA-S group than in ovulatory women. Baseline hormonal differences between the polycystic ovary syndrome groups were limited to those in mean serum DHA and DHA-S levels, which were significantly higher ($p < 0.05$) in the high DHA-S group than in the normal DHA-S group. Both polycystic ovary syndrome groups demonstrated elevations in serum androgens and elevated LH to FSH ratios of 2.0 and 1.7 in the high DHA-S group and the normal DHA-S group, respectively. A reversal of the normal estradiol to estrone ratio also was evident in the normal DHA-S group.

Gonadotropins and estrogens. As shown in Fig. 1, basal gonadotropin levels (mean ± SE) before and during GnRH agonist administration in the high and normal DHA-S groups and ovulatory women are compared with each other. Administration of GnRH agonist for 1 month resulted in marked and significant reductions ($p < 0.05$) of mean serum LH and FSH levels in both groups with polycystic ovary syndrome. These reductions were maintained throughout the entire treatment period. In ovulatory women, gonadotropin concentrations exhibited only modest declines. However, respective serum levels of LH and FSH were similar in all three groups throughout the course of GnRH agonist therapy.

The serum estradiol and estrone responses to GnRH agonist after 1 month of treatment (Fig. 1) also were characterized by marked and significant reductions ($p < 0.05$) in all three groups. Respective serum levels of estradiol and estrone remained low and were similar in all three groups throughout the treatment period. In the case of serum estradiol, levels during treatment approached the limits of sensitivity (10 pg/ml or 36 pmol/L) for the assay.

Progestins. The basal serum progestin levels (mean ± SE) before and during GnRH agonist treatment are shown in Fig. 2. Serum 17-hydroxypregnen-

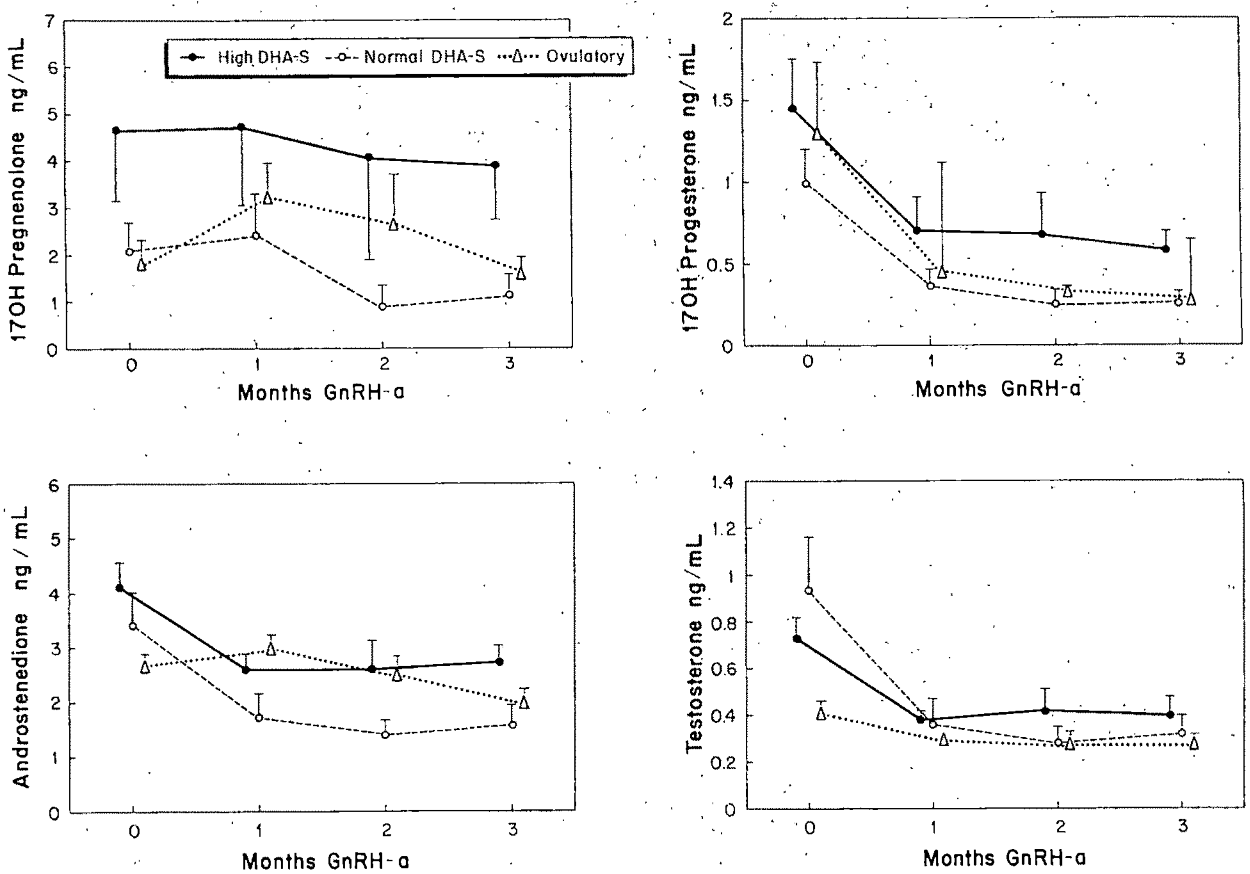

Fig. 2. Basal serum 17-hydroxypregnenolone, 17-hydroxyprogesterone, androstenedione, and testosterone concentrations (mean ± SE) in women with polycystic ovary syndrome with high and normal DHA-S levels and in ovulatory women before and during GnRH agonist *(GnRH-a)* treatment. Factors used to convert data into SI units are 3.003 (17-hydroxypregnenolone), 3.026 (17-hydroxyprogesterone), 3.492 (androstenedione), and 3.467 (testosterone).

olone measurements during treatment never differed significantly from baseline levels in all three groups. In contrast, the considerable reductions in serum 17-hydroxyprogesterone levels that occurred after 1 month of GnRH agonist administration were significant ($p < 0.05$) in both groups with polycystic ovary syndrome. Low serum levels of 17-hydroxyprogesterone persisted in all three groups for the remainder of the study.

Androgens and cortisol. Also depicted in Fig. 2 are the mean basal serum levels of androstenedione and testosterone before and during GnRH agonist administration. A significant reduction in mean serum androstenedione concentrations occurred in the high DHA-S group by 37% ($p = 0.01$) and in the normal DHA-S group by 50% ($p = 0.046$) after the first month of treatment. These low levels were maintained throughout the remainder of the study. In contrast, a modest decline of 23% in the mean serum androstenedione level in ovulatory women was observed only after 3 months of GnRH agonist therapy, which closely approached significance ($p = 0.05$). Serum testosterone levels declined promptly in all three groups. After 1 month of GnRH agonist treatment, the mean serum testosterone levels had fallen significantly by 48% in the high DHA-S group ($p = 0.005$) and by 61% in the normal DHA-S group ($p = 0.015$). Serum testosterone levels remained low and were similar among the three groups for the remainder of the treatment period.

As shown in Fig. 3, the serum concentrations (mean ± SE) of DHA in the high DHA-S group and in ovulatory women, as well as that of DHA-S in the normal DHA-S group and in ovulatory women, remained unaltered throughout GnRH agonist administration. In the normal DHA-S group, the serum DHA levels remained similar to those in ovulatory women during the entire course of GnRH agonist therapy. In the high DHA-S group, the mean serum DHA-S level underwent a progressive linear decline of 24%, to 343.4 ± 39.0 μg/dl (9.1 ± 1.1 μmol/L), which achieved significance ($p = 0.012$) after the third month of GnRH agonist administration. Comparisons between

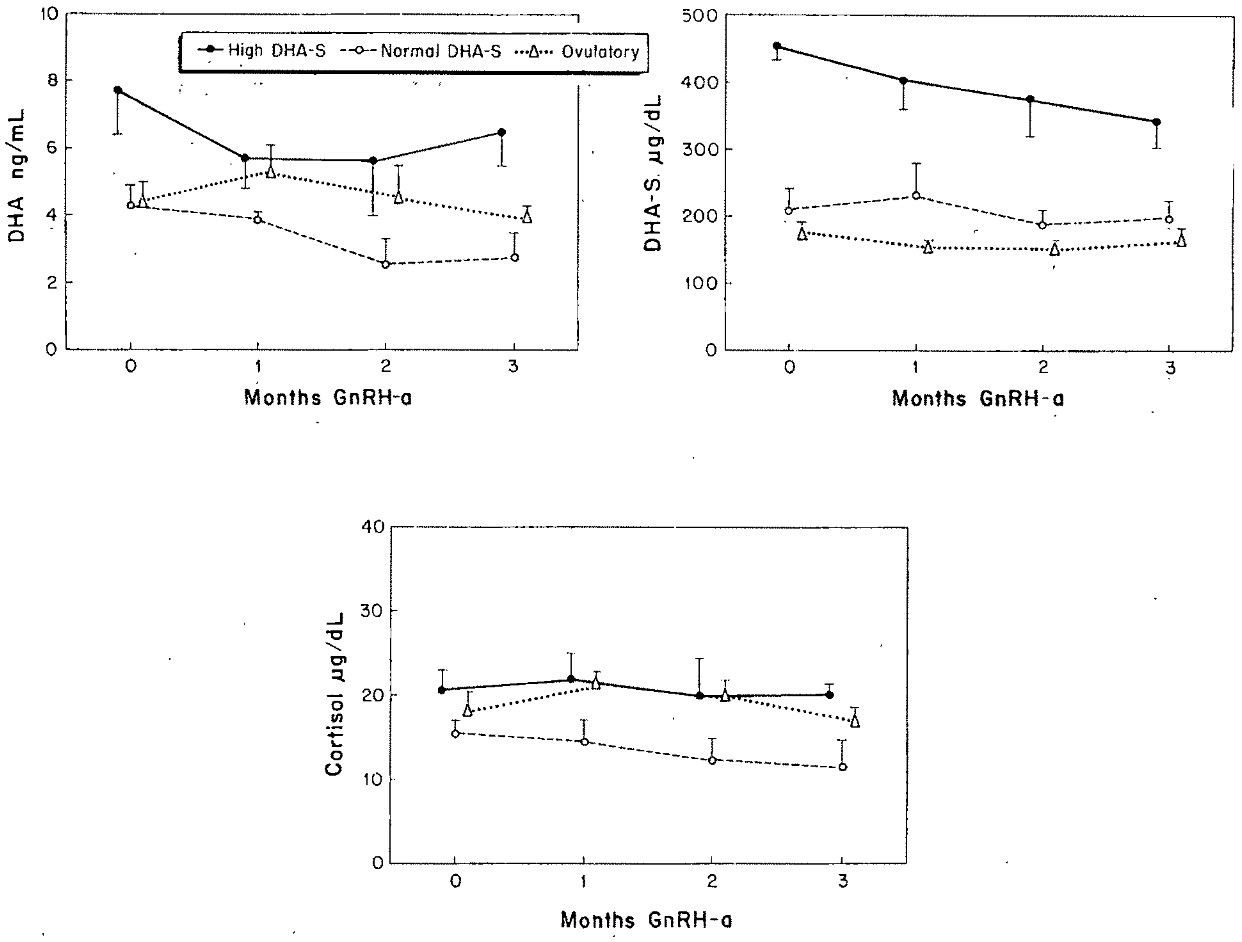

Fig. 3. Basal serum DHA, DHA-S, and cortisol concentrations (mean ± SE) in women with polycystic ovary syndrome with high and normal DHA-S levels and in ovulatory women before and during GnRH agonist *(GnRH-a)* treatment. Factors used to convert data into SI units are 3.467 (DHA), 0.02714 (DHA-S), and 27.59 (cortisol).

this reduction in serum DHA-S with those of either serum estradiol or estrone in the high DHA-S group with the use of regression and correlation yielded correlation coefficients of 0.13 and 0.33, respectively. In contrast, a similar analysis comparing the decline in these estrogens with each other yielded a much higher correlation coefficient of 0.85. The mean DHA-S concentration in the high DHA-S group did not achieve similarity to that of the normal DHA-S group or ovulatory women by the end of the study. Finally, serum cortisol measurements did not change in any of the three groups throughout the course of treatment.

Adrenal dynamic response. The maximal postcorticotropin responses for DHA, androstenedione, 17-hydroxypregnenolone, 17-hydroxyprogesterone, and cortisol were achieved at 60 minutes, then declined significantly or had sustained values at 180 minutes. In contrast, the maximal postcorticotropin response for DHA-S was not achieved until 180 minutes. Similar responses for these steroids have been reported previously.[10] The ratios of 17-hydroxypregnenolone to cortisol, DHA to androstenedione, and 17-hydroxypregnenolone to 17-hydroxyprogesterone and cortisol output were calculated at 60 minutes. The maximum incremental rises of DHA and DHA-S were calculated at 60 and at 180 minutes, respectively.

Adrenal enzyme activities. The postcorticotropin ratios (mean ± SE) of DHA to androstenedione, 17-hydroxypregnenolone to 17-hydroxyprogesterone, and 17-hydroxypregnenolone to cortisol in all three groups before, during, and after GnRH agonist administration are shown in Fig. 4. Before treatment, the mean ratios of all three of these Δ^5- to Δ^4-steroid pairs were similar in all three groups. However, individual analysis of women with polycystic ovary syndrome suggests altered 3β-hydroxysteroid dehydrogenase activity in two subjects (No. 4 and No. 10) in the high DHA-S group depicted by triangles in Figs. 4 and 5, who showed the greatest decline in basal secretion of DHA-S (34% and 40%, respectively) during treatment. Before GnRH agonist administration, subject 10 met all the criteria for 3β-hydroxysteroid dehydrogenase de-

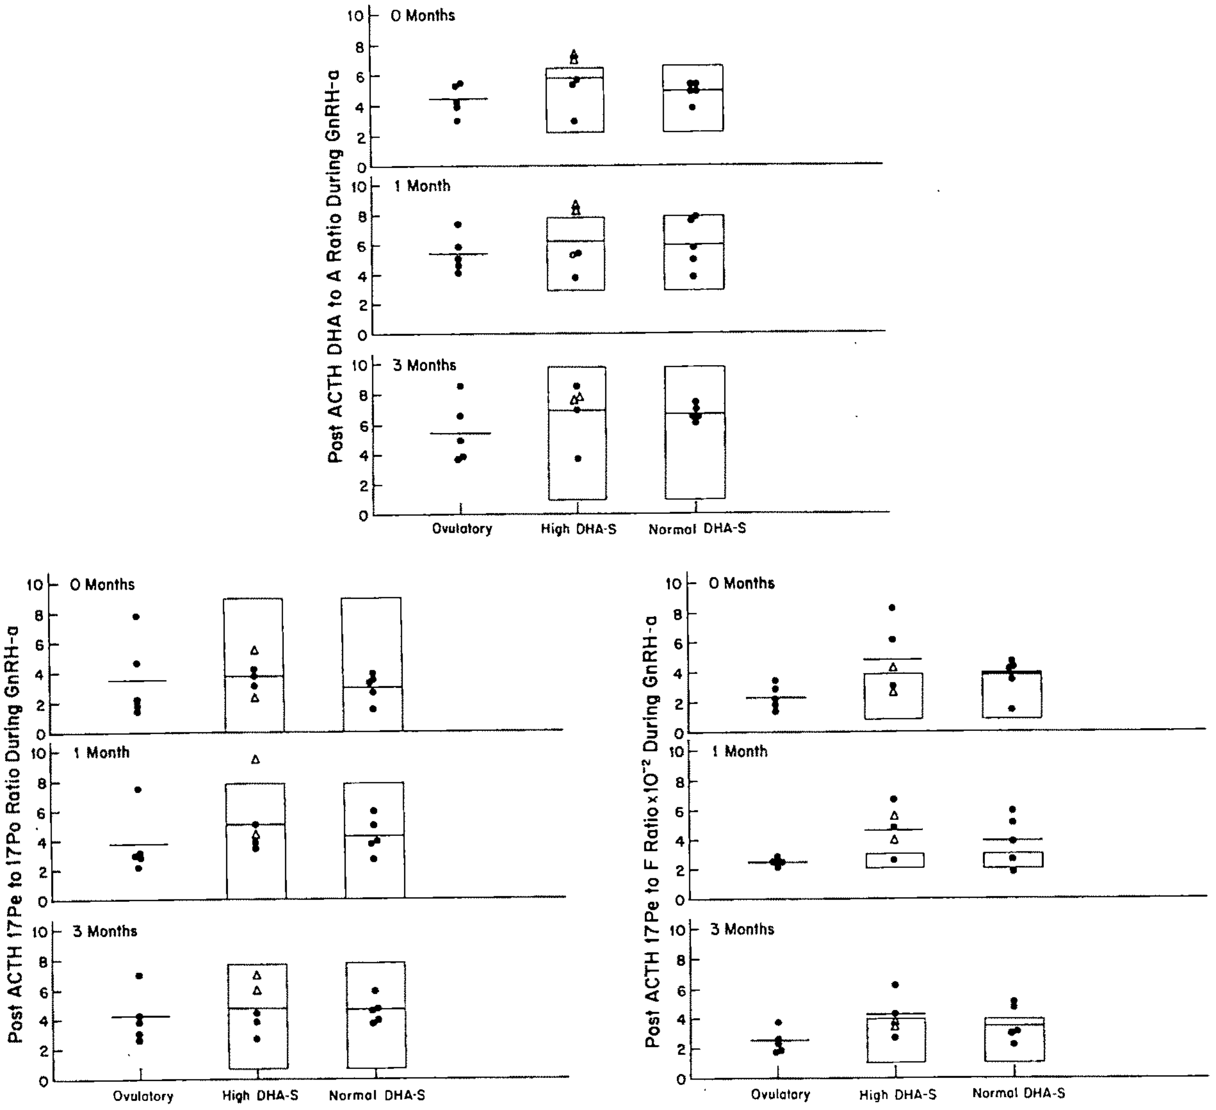

Fig. 4. Postcorticotropin ratios of DHA to androstenedione *(A)*, 17-hydroxypregnenolone *(17Pe)* to 17-hydroxyprogesterone *(17Po)*, and 17-hydroxypregnenolone to cortisol *(F)* for women with polycystic ovary syndrome with high and normal DHA-S levels and in ovulatory women at 0, 1, and 3 months of GnRH agonist *(GnRH-a)* treatment. Two women with high levels of DHA-S (△) met the criteria for 3β-hydroxysteroid dehydrogenase deficiency at 0 or 1 month or both of these intervals.

ficiency whereas subject 4 met only two of three criteria. After 1 month of GnRH agonist treatment, both of these subjects showed all the criteria for 3β-hydroxysteroid dehydrogenase deficiency. End-of-treatment values in both subjects revealed postcorticotropin levels of DHA and 17-hydroxypregnenolone that remained similar to the 1-month treatment values but postcorticotropin ratios of DHA to androstenedione and 17-hydroxypregnenolone to cortisol that were <2 SD above the mean of ovulatory women. These latter findings suggest a resolution of the 3β-hydroxysteroid dehydrogenase deficiency in response to GnRH agonist therapy.

None of the women with polycystic ovary syndrome from either the high or normal DHA-S group met the criteria for 17,20-lyase hyperactivity during baseline dynamic testing. There was also no evidence of altered 17,20-lyase activity in women with polycystic ovary syndrome either before or in response to GnRH agonist therapy when the mean substrate to product ratios for this enzyme were compared among all three groups.

Cortisol output. As shown in Fig. 5, cortisol output (mean ± SE) in the high DHA-S group (27.3 ± 0.9 μg/dl or 753.2 ± 24.8 nmol/L), in the normal DHA-S group (29.8 ± 1.9 μg/dl or 822.2 ± 57.4 nmol/L) and in ovulatory women (25.3 ± 30.0 μg/dl or 698.0 ± 82.8 nmol/L) were not significantly different before GnRH agonist administration and remained similar af-

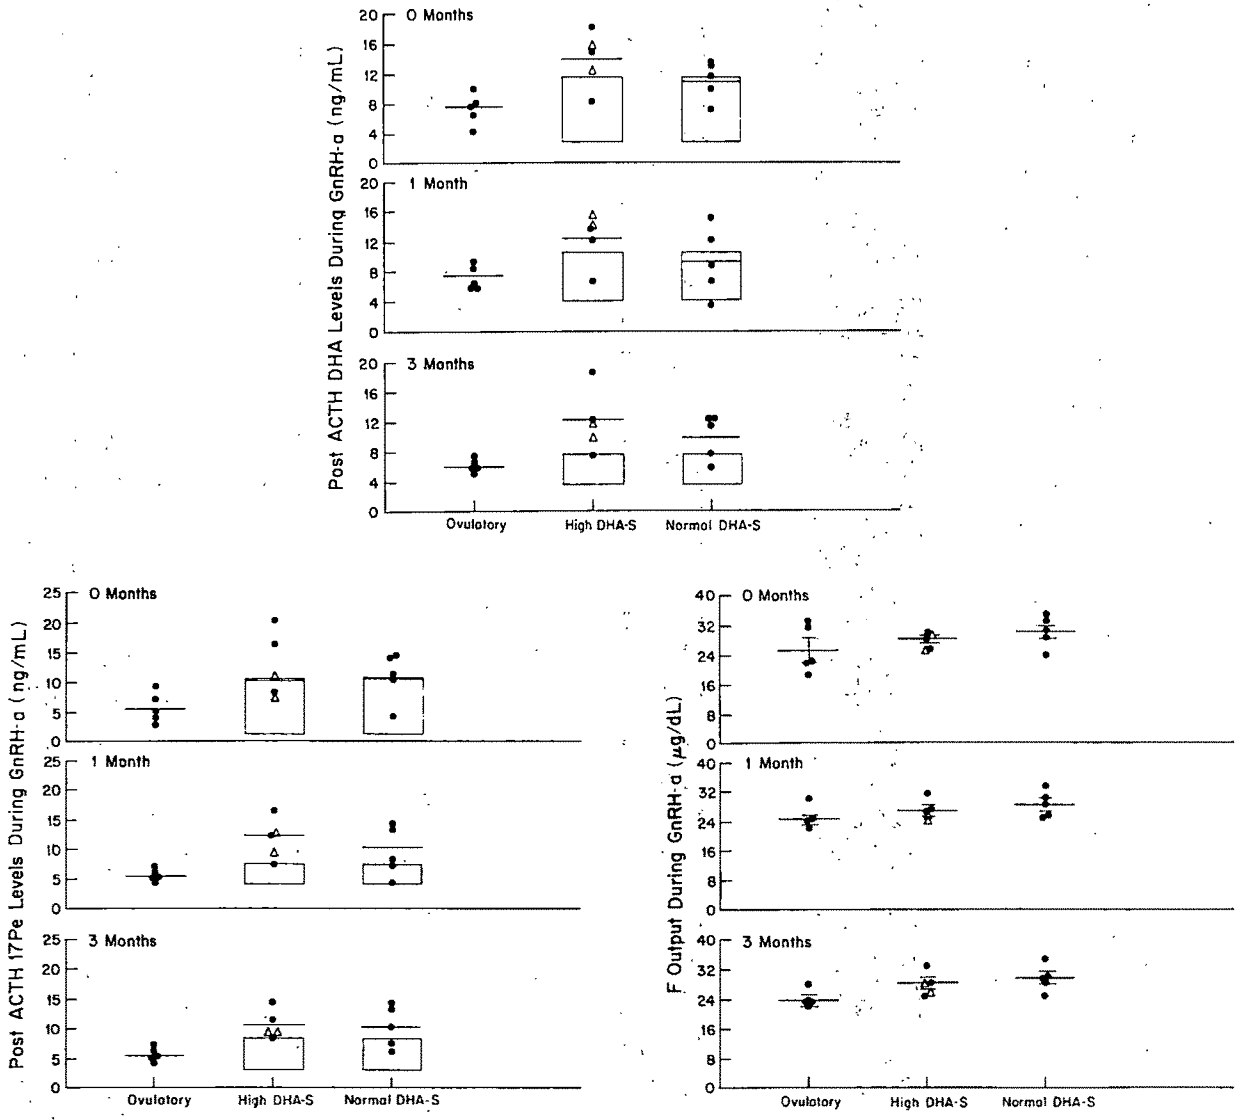

Fig. 5. Postcorticotropin levels of DHA and 17-hydroxypregnenolone *(17Pe)*, as well as cortisol *(F)* output, in women with polycystic ovary syndrome with high and normal DHA-S levels and in ovulatory women at 0, 1, and 3 months of GnRH agonist *(GnRH-a)* treatment. Two women with high DHA-S levels (Δ) met criteria for 3β-hydroxysteroid dehydrogenase deficiency at 0 or 1 month or both of these intervals.

ter 1 month of treatment. By the end of the study cortisol output in the high DHA-S group (28.6 ± 1.1 µg/dl or 789.1 ± 30.3 nmol/L) was again similar to that in the normal DHA-S group (29.4 ± 1.6 µg/dl or 800.1 ± 44.1 nmol/L) but was significantly greater ($p = 0.014$) by 19% compared with that in ovulatory women (24.0 ± 1.0 µg/dl or 662.2 ± 27.6 nmol/L).

Adrenal androgen capacity. Measurements of the maximum incremental rise (mean ± SE) representing the adrenal capacity for DHA and DHA-S before, during, and after GnRH agonist treatment are shown in Fig. 6. The mean baseline maximum incremental rises of both adrenal androgens were greater in the high DHA-S group than in the normal DHA-S group and greater in the normal DHA-S group than in ovulatory women. Throughout the course of GnRH agonist administration, the difference in maximum incremental rises of either adrenal androgen between the high and normal DHA-S group did not achieve significance. However, the maximum incremental rises of both adrenal androgens were significantly greater ($p < 0.05$) in the high DHA-S group than in ovulatory women after 1 month and 3 months of GnRH agonist therapy. In spite of the differences between either group with polycystic ovary syndrome and ovulatory women by the end of the study, the maximum incremental rises of DHA and DHA-S remained unaltered in both groups with polycystic ovary syndrome compared with respective baselines throughout the entire treatment period. Therefore the pattern of adrenal capacity ob-

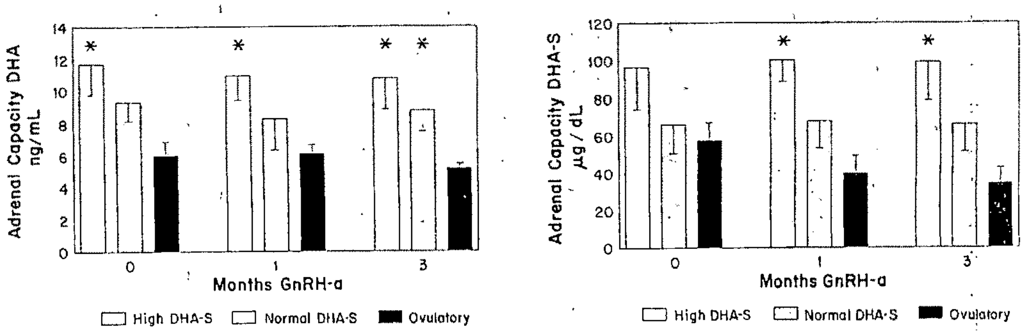

Fig. 6. Measurements of maximum incremental rise (mean ± SE) representing adrenal capacity for DHA and DHA-S in women with polycystic ovary syndrome with high and normal DHA-S levels and in ovulatory women at 0, 1, and 3 months of GnRH agonist *(GnRH-a)* treatment. *Asterisk,* Significant difference ($p < 0.05$) between either group of women with polycystic ovary syndrome and ovulatory women.

served during baseline dynamic testing (the high DHA-S group > the normal DHA-S group > ovulatory women) persisted in both adrenal androgens on completion of GnRH agonist therapy.

Comment

The baseline hormonal concentrations in women with polycystic ovary syndrome were similar to previously reported results for this syndrome.[11] In both groups with polycystic ovary syndrome, complete suppression of ovarian steroidogenesis was apparent after 1 month of GnRH agonist treatment. This is evident by the reductions in respective basal serum concentrations of estradiol, estrone, 17-hydroxyprogesterone, androstenedione, and testosterone to similar levels during this time. Whereas basal serum estradiol levels were nearly undetectable, the detectable levels of basal serum estrone, 17-hydroxyprogesterone, androstenedione, and testosterone were most likely derived from the adrenal glands, either by direct secretion or by peripheral conversion of an adrenal precursor. The persistence of this phenomenon for the entire 3 months of therapy is consistent with a previous report[4] indicating that prolonged GnRH agonist administration induces and maintains declines in ovarian steroids in the castrate range.

In all three groups it is likely that the sustained declines in basal serum FSH during therapy caused the corresponding decreases in basal serum estradiol and estrone. In addition, the sustained declines in basal serum LH throughout GnRH agonist treatment coincided with declines in basal serum androstenedione, testosterone, and 17-hydroxyprogesterone. Results from Rittmaster[7] suggest that optimal suppression of basal serum LH with a dose of leuprolide acetate similar to that used in our study is required for maximum reductions of ovarian testosterone concentrations in women with polycystic ovary syndrome, even though serum estradiol levels can be easily suppressed on half of the GnRH agonist dose selected. In fact, the mean concentrations of testosterone observed during treatment in the women with polycystic ovary syndrome in our study (48% and 61% for the high and normal DHA-S groups, respectively) were consistent with the maximal GnRH agonist suppressed levels (56%) previously described for this syndrome.[7]

It is unlikely that GnRH agonist administration is capable of directly affecting adrenal steroidogenesis. Basal serum cortisol, the major secretory product of the adrenal, remained unaltered within the normal range in all three groups for the entire 3 months of treatment. In addition, the basal serum concentrations of DHA and DHA-S, androgens of predominantly adrenal origin, remained within the normal range in the normal DHA-S group and in ovulatory women throughout the course of the study. These findings are well documented by previous investigators.[3, 4, 8] Moreover, the responses of these adrenal androgens in the normal DHA-S group and in ovulatory women to GnRH agonist–induced ovarian suppression suggest that ovarian steroids are not responsible for the maintenance of normal adrenal androgen secretion in reproductive-age women, regardless of whether they are ovulatory or have polycystic ovary syndrome.

In contrast, ovarian steroids appear to be capable of promoting excess adrenal androgen secretion. This is evident in the high DHA-S group by the gradual but significant decline in basal serum DHA-S toward the normal range in response to 3 months of GnRH agonist administration. This pattern of response in serum DHA-S is unlikely to be ovarian, given its poor correlation with the immediate sharp decline in ovarian estrogens and the lack of significant change in its immediate precursor, DHA in the high DHA-S group. It is well established that DHA-S is quantitatively the most important adrenal androgen, given its high serum concentrations, its long half-life, and its minimal diurnal or episodic variation.[12] Consequently, the significant elevation in the pretreatment levels of basal serum DHA-S in the high DHA-S group is the most sensitive indicator of adrenal involvement in polycystic ovary syndrome,[1, 13] and the change in basal serum DHA-S in this group during GnRH agonist therapy is more likely than that of DHA to be indicative of alteration in adrenal function.

Three months of GnRH agonist administration is insufficient to correct adrenal dysfunction in the high DHA-S group. This is evident by the lack of similarity between the end-of-treatment serum DHA-S level in the high DHA-S group and the normal unaltered DHA-S concentrations in the other two groups. Although the GnRH agonist treatment length was chosen arbitrarily, consideration was given to select a reasonable period of time for sufficient adrenal morphologic alterations to occur that would cause an appropriate change in adrenal steroidogenesis.[14] However, further studies are required to determine the appropriate length of GnRH agonist administration for normalization or stabilization of basal DHA-S levels in the high DHA-S group.

It is possible that changes in adrenocortical steroidogenic enzyme activities in response to GnRH agonist treatment resulted in the normalizing trend in basal serum DHA-S secretion in the high DHA-S group. Our data suggest that some, but not all, subjects in the high DHA-S group demonstrated alteration in 3β-hydroxysteroid dehydrogenase activity. Dynamic testing before and after 1 month of GnRH agonist treatment revealed evidence of 3β-hydroxysteroid dehydrogenase deficiency in two subjects in the high DHA-S group during an interval that involved the complete elimination of ovarian steroids from the circulation.[15] After 3 months of treatment, however, normalization of 3β-hydroxysteroid dehydrogenase activity could be demonstrated in each of these individuals. 3β-Hydroxysteroid dehydrogenase is a key branch point enzyme whose activity must remain low for adrenal androgen synthesis to be favored.[16] It is possible that ovarian steroids exert an extrinsic inhibitory influence on 3β-hydroxysteroid dehydrogenase activity leading to the elevations in serum DHA-S levels in some subjects in the high DHA-S group. However, the exact mechanism by which ovarian steroids could cause this inhibition and the possible role of other factors such as insulin or insulin-like growth factors is beyond the scope of this study. Other factors must be involved since the remaining women with polycystic ovary syndrome in the high DHA-S group did not have 3β-hydroxysteroid dehydrogenase deficiency and because further declines in serum DHA-S concentrations were not yet achieved in spite of normalization of 3β-hydroxysteroid dehydrogenase activity in the individuals affected. Nevertheless, these findings, along with evidence of normal or better glucocorticoid performance (cortisol output) in the high DHA-S group, support the contention that mild 3β-hydroxysteroid dehydrogenase deficiency can be acquired and is not always a primary genetic defect. In fact, a genetic marker for this enzyme abnormality has yet to be identified.

Examination of adrenal androgen capacity did not indicate that ovarian steroids induce adrenal androgen hyperresponsiveness to corticotropin as a cause for adrenal involvement in polycystic ovary syndrome. First of all, the greater adrenal androgen capacity in the high DHA-S group as compared with ovulatory women during baseline testing was not a phenomenon unique to this group, because baseline adrenal androgen capacity in the normal DHA-S group also was markedly increased and only slightly lower than that in the high DHA-S group. These findings confirm those in previous studies that separately reported increased adrenal capacity for DHA in women with polycystic ovary syndrome similar to those in the normal DHA-S group[17] and for DHA-S in women with polycystic ovary syndrome similar to those in the high DHA-S group.[1] In addition, adrenal androgen capacity remained unaltered in both groups with polycystic ovary syndrome throughout the course of GnRH agonist administration. Determination of adrenal androgen capacity requires the use of pharmacologic doses of corticotropin; therefore it is still possible for the adrenal androgen response to normal levels of circulating corticotropin present in all women with polycystic ovary syndrome[1, 18] to be different in each of the two groups. In fact, women with polycystic ovary syndrome similar to those in the normal DHA-S group have a normal adrenal androgen response to physiologic doses of corticotropin from a dexamethasone-suppressed baseline (adrenal sensitivity).[17] Therefore adrenal androgen capacity does not reflect the physiologic circumstance, and the lack of change in this parameter in women with polycystic ovary syndrome during GnRH agonist therapy only indicates that the pharmacologic response to corticotropin is independent of ovarian steroid influence.

In summary, suppression of ovarian steroids during GnRH agonist administration for 3 months resulted in a decline in basal serum DHA-S in women with polycystic ovary syndrome who have adrenal involvement. This alteration in serum DHA-S, the most sensitive marker of adrenal androgen production, suggests that ovarian steroids are capable of promoting excess adrenal androgen secretion. However, a GnRH agonist treatment length of 3 months was insufficient for serum DHA-S levels to fall to the normal range in this group. Adrenal 3β-hydroxysteroid dehydrogenase deficiency may be induced by ovarian steroids to cause elevations in basal serum DHA-S in some women with polycystic ovary syndrome who have adrenal involvement, but the exact mechanism for this phenomenon remains to be elucidated. In polycystic ovary syndrome, ovarian steroids have no impact on adrenal androgen capacity. However, the possibility cannot be excluded that women with polycystic ovary syndrome who have adrenal involvement also have increased adrenal androgen sensitivity that may or may not be under the influence of ovarian steroids.

Management of fetal hemolytic disease by cordocentesis

I. Prediction of fetal anemia

Between January 1985 and November 1990, 128 pregnancies complicated by maternal red blood cell alloimmunization were referred to our Fetal Diagnosis and Treatment Unit. We examined the premise that an evaluation of fetal blood would accurately identify fetuses at risk of requiring antenatal transfusion therapy. Two hundred seventy-two diagnostic cordocenteses were performed. Criteria for the timing of repeat cordocenteses were developed retrospectively on the basis of the fetal hematocrit values, reticulocyte counts, and direct Coombs' test results of the first 84 pregnancies. These criteria were tested and confirmed prospectively on the next 44 pregnancies. On the basis of the first blood sample, four hematologic patterns (and their distributions) were identified in the 98 antigen-positive fetuses. *Pattern 1:* fetuses at low risk of having significant antenatal anemia (hematocrit <30%) (n = 11, 11%). These fetuses had normal hematocrit values and reticulocyte counts coupled with negative or trace-positive direct Coombs' test. No fetus in this group had significant antenatal anemia. *Pattern 2:* fetuses at intermediate risk of having anemia (n = 29, 31%). *Pattern 2 fetuses* had normal hematocrit values and either direct Coombs' titers of more than trace ≤2+ and normal reticulocyte counts or low reticulocyte counts (<2.5th percentile for gestation). Twenty-one percent (n = 6) of fetuses in pattern 2 had significant antenatal anemia. *Patterns 3 and 4:* fetuses at greatest risk of having severe anemia. These fetuses had normal hematocrit values associated with either reticulocyte counts >97.5th percentile for gestation or a direct Coombs' test ≥3+ (pattern 3, n = 49, 50%) or both, or a mild anemia (>30% but <2.5th percentile for gestation) (pattern 4, n = 9, 10%). Eighty percent (n = 39) of fetuses with pattern 3 and 90% (n = 8) with pattern 4 developed a hematocrit value <30%. We conclude that evaluation of fetal hemolytic disease with a fetal blood specimen permits the identification of fetuses at high risk of having antenatal anemia. (AM J OBSTET GYNECOL 1991;165:546-53.)

Key words: Fetal hemolytic disease, cordocentesis, fetal intravascular transfusion, immune hydrops fetalis, neonatal hyperbilirubinemia

Fetal hemolytic disease caused by maternal alloimmunization remains a significant clinical problem. Anemia is the primary fetal pathophysiologic event that may lead to edema (anasarca), fetal cardiac failure, and death. The diagnosis and treatment of fetal hemolytic disease has changed little since the landmark work of Liley and others in the late 1950s and the 1960s.[1-5] These authors developed a diagnostic and therapeutic protocol that indirectly assessed fetal hemoglobin concentration on the basis of the measurement of amniotic fluid bilirubin levels as reflected by the change in optical density measurements of 450 nm (ΔOD_{450}).[1, 3] In fetuses with evidence of significant hemolysis, fetal intraperitoneal transfusion was administered. Although intrauterine intravascular transfusion has supplanted intraperitoneal transfusion in some centers,[6-9] serial measurement of the amniotic fluid ΔOD_{450} to identify candidates for fetal blood sampling remains the diagnostic mainstay, and affected fetuses (treated or untreated) are routinely delivered at <37 weeks.[4, 5, 10, 11]

A direct evaluation of the fetus would be preferable to evaluation of amniotic fluid for a number of reasons. First, the ΔOD_{450} is an indirect reflection of hematocrit value, and there is a wide range in the fetal hematocrit value for a given ΔOD_{450} at a gestational age.[3, 12, 13] Though sensitive, amniotic fluid studies are not specific. The ΔOD_{450} can be altered by contamination with blood, other fetal diseases (e.g., congenital hepatitis), and maternal diseases (e.g., sickle cell anemia). Second,

the initial studies of anti-D hemolytic disease that formed the basis for the Liley curve were begun at 28 weeks' gestation. It is now possible to treat fetuses with severe anemia as early as 18 weeks. Predictions of disease severity on the basis of amniotic fluid nomograms extrapolated back to the midsecond trimester are less accurate than predictions made in the third trimester, because the normal ΔOD_{450} in the second trimester is zone II rather than zone I of the Liley curve.[12] Third, the ΔOD_{450} system requires at least two amniocenteses to ascertain a pattern. Fourth, the amniotic fluid method was developed according to anti-D hemolytic disease, and the results may differ with hemolytic disease caused by other antibodies.[14, 15]

In 1985 we began to examine the premise that evaluation of fetal blood rather than amniotic fluid would more accurately predict the severity of fetal disease and the need for transfusion. Because we and others had already observed a poor relationship between the fetal hematocrit value and the ΔOD_{450},[12, 13] our goal was to establish a management scheme for red blood cell alloimmunization based on fetal blood testing. We speculated that such direct testing would minimize the number of invasive procedures and prevent unnecessary preterm delivery.

Material and methods

The University of Iowa Hospital and Clinic is the tertiary care unit for the state of Iowa. There are well-established lines of referral to the university for the evaluation of maternal alloimmunization. In our laboratory, a maternal indirect Coombs' titer ≥8 has traditionally been used as an indication for amniocentesis because severe neonatal hemolytic disease has occurred at 8 but not below. Cordocentesis was offered when the maternal indirect Coombs' test revealed an immunoglobulin G titer ≥8 and either (1) ΔOD_{450} in zone II or higher before referral, (2) known or suspected paternal heterozygosity, or (3) history of a prior, significantly affected fetus or neonate. After documenting the safety of cordocentesis,[16] we offered cordocentesis for the same indications as amniocentesis.

We sought to perform the first procedure between 24 and 26 weeks unless the clinical history or ultrasonographic examination suggested a need for an earlier sample. A direct Coombs' test, red blood cell antibody elution, and identification were performed by the central hospital laboratory on the first fetal sample. Complete blood cell and reticulocyte counts were performed for each fetal sample. Not all values were available for all fetuses; therefore the totals are low in some of the data sets to be presented.

The technique used for cordocentesis has previously been described in detail.[16] In brief, a 22-gauge spinal needle was held in the ultrasonographic plane of a 5 MHz sector transducer with a fixed-needle guide (CIVCO, Kalona, Iowa). Pancuronium bromide (0.3 mg/kg estimated fetal weight intravenously or intramuscularly) was given when fetal movement was believed to pose a risk. We prefer the umbilical vein to the umbilical artery for sampling to minimize fetal morbidity. To minimize the risk of exacerbating mild disease, an effort was made to avoid puncturing the placenta when results of the maternal Coombs' test were relatively low (<128). In these instances maternal serum testing was repeated at 4-week intervals to identify a significant increase in the titer (two-tube or more dilution).

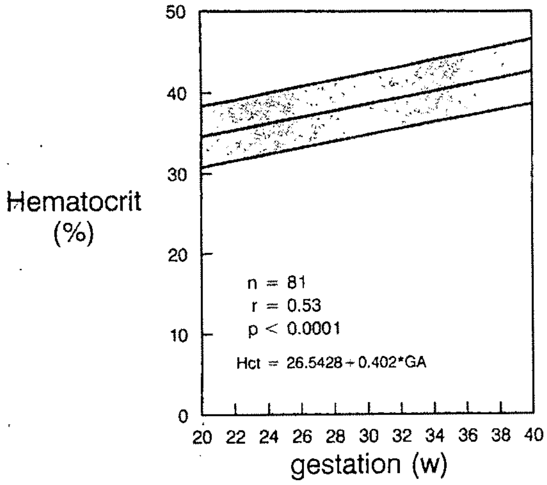

Fig. 1. Ninety-five percent confidence intervals for normal hematocrit values across gestational age *(GA)* (n = 81). *W*, weeks.

The control values were derived from fetuses referred for a variety of indications[16] who ultimately were shown to be free of disease. The 95% confidence intervals of the data were calculated for both the hematocrit count and the percentage of reticulocytes. Transfusion therapy was reserved for fetuses with severe anemia (defined as a hematocrit value <30%). A hematocrit value of 30% was <2.5th percentile for all control fetuses ≥20 weeks. The confidence interval for the hematocrit value was based on the linear regression of hematocrit value versus gestational age (r = 0.55, p < 0.0001). Because the correlation coefficient is fairly low, this type of calculation gave the widest normal range (Fig. 1). By taking this approach we believed we could avoid treating fetuses with borderline disease. For similar reasons we used the actual data rather than the regression (r = −0.54, p < 0.0001) to calculate the confidence intervals for the reticulocyte count across gestation. This conservative approach yields a narrower normal range (Table I). Thus we could be confident that any fetus said to have a normal count was indeed normal.

*In one patient neither direct Coombs' test nor reticulocyte count was done.

All records were maintained prospectively in a computer data base. The results are presented as the mean ± 1 SD unless stated otherwise. Analyses included paired and unpaired Student's t tests, cross-tabulation, and stepwise multiple regression. A $p \leq 0.05$ was considered to indicate a significant difference.

Results

Through November 1990, 128 consecutive pregnant women who fulfilled the criteria were evaluated for alloimmunization to a variety of antigens associated with fetal hemolytic disease (Table II). Fifty-five percent were alloimmunized to the D antigen, although two thirds of these women had one or more additional immunoglobulin G antibodies present. The mean gravidity for the entire group was 3.5 ± 1.4 (range 1 through 9) and the parity was 1.9 ± 1 (range 0 through 5). The two primigravida women had become sensitized after transfusion; each had an anti-Kell titer of 256. Seventy percent of the patients had been pregnant 2 or more times.

Two hundred seventy-two diagnostic cordocenteses were performed. The mean gestational age at the time the first specimen was taken was 26 ± 4 weeks (range 18 to 34 weeks). Twenty-nine (23%) fetuses were antigen negative.

Fetal bradycardia occurred after 4% of the procedures, more commonly when the umbilical artery was punctured: 15% versus 2.8% ($p < 0.05$). One antigen-positive fetus was delivered by emergency cesarean section at 28 weeks because of prolonged bradycardia associated with cordocentesis. The infant was discharged from the nursery after having severe respiratory distress syndrome.

One affected fetus whose sample was taken at 21 weeks died 2½ weeks after the procedure and 3 days after ultrasonography had documented both viability and normal interval growth. Although the cause of death could not be determined at autopsy, there was no evidence that the death was procedure related.

We investigated whether the antenatal development of a hematocrit value <30% could be predicted from the fetal blood tests, beginning with the 53 fetuses who were initially seen with severe anemia ($n = 18$) or in whom severe anemia developed ($n = 35$). There was a positive relationship between the trimester in which the anemia developed and the result of the direct Coombs' test ($p < 0.05$, Table IIIA). Sixty-two percent of fetuses in whom severe anemia developed in the second trimester had direct Coombs' test results of 3+ or 4+. A similar trend was observed when the initial reticulocyte count was above the 97.5th percentile ($p = 0.07$, Table IIIB). The direct Coombs' titer was ≤2+ in each of the six instances in which the reticulocyte count was below the 2.5th percentile. Finally, there was a positive correlation between the direct Coombs' test result and the fetal reticulocyte count ($p = 0.015$). Thus the fetus at greatest risk for severe disease early in pregnancy either had a strong stimulus for hemolysis (i.e., a large amount of antibody coating the red blood cells) or had evidence of heightened red blood cell production.

When these same tests were applied to all antigen-positive fetuses, the relationships between the direct Coombs' test, reticulocyte count, and development of severe antenatal anemia were confirmed (Table IV). A reticulocyte count >97.5th percentile predicted the development of a hematocrit value <30% before delivery 83% of the time. Similarly, a direct Coombs' test result ≥3+ had a positive predictive value of 79% for the development of severe anemia.

On the basis of these relationships, we developed a scheme to manage the repetition of cordocentesis in the antigen-positive fetus. Four patterns were identified on the basis of the first blood sample taken. Management is summarized in Table V. The distribution of fetuses is summarized in Fig. 2. The 18 fetuses with a hematocrit value <30% when first seen were assigned to a pattern on the basis of their direct Coombs' test results and reticulocyte counts.

Pattern 1. Fetuses at lowest risk of developing a hematocrit value <30% before delivery (n = 11, 11%) had a normal hematocrit value, normal reticulocyte count, and a direct Coombs' test result that was either negative or trace positive when first sampled. These fetuses were monitored by serial ultrasonography. If the initial maternal antibody titer was low (<128), the indirect Coombs' test was repeated every 4 weeks in search of a twofold or more rise in titer. This occurred once. When the cordocentesis was repeated, the fetal hematologic profile was normal. These neonates were delivered at term. No neonate in this low-risk group was reported to have anemia at birth.

Pattern 2. Fetuses at intermediate risk of a hematocrit value <30% developing (n = 29, 31%) had a normal hematocrit percentage, a direct Coombs' titer of 1 or 2+, and a normal or low reticulocyte count when first sampled. Cordocentesis was repeated in 5 to 6 weeks. Ultrasonography was performed between procedures at 2- to 3-week intervals. This interval was initially selected so that transfusion therapy could be initiated if necessary before late in gestation (<32 weeks). As our experience has grown, we have transfused a fetus for the first time as late as 36 weeks rather than deliver prematurely. Blood sampling was not repeated a third time if the second hematocrit value and reticulocyte count were still normal. Instead, the pregnancy was monitored by ultrasonography every 2 weeks; delivery was planned for 38 weeks. Six (21%) fetuses in this group required transfusion late in gestation (29 to 36 weeks). In six of the seven, the anemia evolved slowly over 5 to 8 weeks. Two pregnancies requiring third-trimester transfusion were associated with maternal indirect Coombs' titers of 16 and 8.

Table IIIA. Relationship between results of initial direct Coombs' test and trimester in which severe anemia developed

TOTAL	5		18		21		44

Not all data available for all fetuses.

Fisher exact test, p = 0.04 for risk of transfusion in the second trimester if direct Coombs' test results ≥3+ compared with all others.

Table IIIB. Relationship between initial reticulocyte count and trimester in which severe anemia developed

Trimester hematocrit value <30th percentile	*Reticulocyte count*						
	<2.5th percentile		*Normal*		*>97.5th percentile*		
	No.	*%*	*No.*	*%*	*No.*	*%*	*Total*
2	1	5	2	11	16	84	19
3	5	22	4	17	14	61	23
TOTAL	6		6		30		42

Not all data available for all fetuses.

Patterns 3 and 4. The third and fourth groups were at high risk of developing a hematocrit value <30%. They were characterized by either a normal hematocrit value with a direct Coombs' titer ≥3+ or a reticulocyte count >97.5th percentile or both (pattern 3, n = 49, 50%) or a mild anemia (i.e., hematocrit value ≥30% but <2.5th percentile for gestation) (pattern 4, n = 9, 9%). Each of the 18 fetuses with a hematocrit value <30% when first studied had, in addition to anemia, blood studies consistent with pattern 3. Cordocentesis was repeated at 1- to 2-week intervals. Ultrasonography was performed between procedures. Severe anemia developed in some of the fetuses; in 50% it did so in the second trimester. Eighty percent (n = 39) of fetuses with pattern 3 and 89% (n = 8) with pattern 4 had severe antenatal anemia.

Patterns 3 and 4 are similar but not identical. Several fetuses with pattern 4 had normal or low reticulocyte counts and a 1 to 2+ direct Coombs' titer. They would have been placed in a lower risk pattern and monitored less often if not for their low hematocrit values. Yet all

*Positive predictive value for reticulocyte count >97.5th percentile for severe anemia = 33 of 40 (83%); $\chi^2 = 26.1$ for cross-tabulation of reticulocyte groups, $p < 0.0001$.

†$\chi^2 = 10.6$ for cross-tabulation of direct Coombs' test groups, $p < 0.0001$.

‡Positive predictive value of direct Coombs' test resuts of 3+, 4+ for severe anemia = 22 of 28 (79%).

but one pattern 4 fetus became candidates for transfusion therapy before delivery. It may be that fetuses with pattern 4 were actually in a transition stage and if sampled earlier would have had a normal hematocrit value and been placed in either pattern 2 or 3. Two fetuses (one pattern 3 and one pattern 4) developed hydrops within 2 weeks of their first cordocentesis. In both instances, the placenta was posterior and the maternal indirect Coombs' titer was >1024 before evaluation. This experience stresses the importance of the interval ultrasonography. Three fetuses with patterns 3 or 4 in whom transfusion became necessary had a maternal indirect Coombs' titer ≤64.

Fetuses with anti-D antibody were significantly more likely to develop a hematocrit value <30% than those with a non-anti-D antibody (39/71 vs 16/57, $\chi^2 = 8.7$, $p = 0.003$). However, the patterns were equally predictive of the need for transfusion in D and non-D disease, suggesting that even though the stimuli for hemolysis varied, the responses to hemolysis were similar. The definitions of the patterns and the management of fetuses within each group are shown in Table V.

Although the data presented in the tables were based on all pregnancies evaluated through November 1990, the diagnostic scheme has remained unchanged since August 1989. This allowed us to examine the performance of the protocol prospectively in the 44 patients evaluated from September 1989 to the close of the study November 1990. In this group, 8 (18%) fetuses were antigen negative. The pattern distribution of antigen-positive fetuses and the incidence of transfusion were pattern I: $n = 7$, 0 (0%) transfused; pattern II: $n = 15$, six (40%) transfused; pattern III: $n = 13$, 8 (62%) transfused; and pattern IV: $n = 1$, 1 (100%) transfused.

Comment

Obtaining a fetal blood sample permits an accurate measurement of the fetal hematocrit. We have demonstrated that by measuring the indicators that reflect the potential for hemolysis (direct Coombs' titer) and the fetal response to hemolysis (the hematocrit and the reticulocyte count) nonanemic fetuses at greatest risk of developing anemia can be prospectively identified. Our experience with the direct evaluation of fetal hemolytic disease supports the findings of a smaller series by MacKenzie et al.[17]

We have constructed four patterns of fetal hemolytic disease that permit stratification on the basis of a fetus's risk of developing a significant antenatal anemia. In all, 31% of pregnancies studied required only one cordocentesis (29 antigen-negative fetuses plus 11 pattern 1 fetuses), and another 18% required only two procedures (23 fetuses with pattern 2 not requiring transfusion therapy). Eighty-five percent of the remaining fetuses had or developed a hematocrit value <30% and were candidates for transfusion therapy.

The antigen-positive fetuses at lowest risk of developing anemia (pattern 1) had a normal hematocrit value and reticulocyte count plus a negative to trace-positive direct Coombs' test result. These pregnancies were followed with periodic ultrasonography for the detection of hydrops. Otherwise, the women were delivered at term. To date, no fetus in this group has been reported to have been born with anemia.

Included in the intermediate-risk group (pattern 2) were several fetuses who failed to respond to their low-grade hemolysis with a reticulocytosis. Surprisingly, the reticulocyte count was actually below the 2.5th percentile for gestation in some of these fetuses. It is unlikely that the low reticulocyte count resulted from hemolysis of the reticulocyte before it entered the circulation because the fetal hematocrit value declined slowly. When transfusion therapy for this group was indicated, it was most often in the third trimester. It would appear that for some yet-to-be-defined reason, these fetuses have a blunted erythropoietic response to anemia.

In fetuses at greatest risk of developing anemia, the hematocrit value was already <2.5th percentile but >30% when first evaluated (pattern 4), or the hematocrit value was in the normal range but was associated

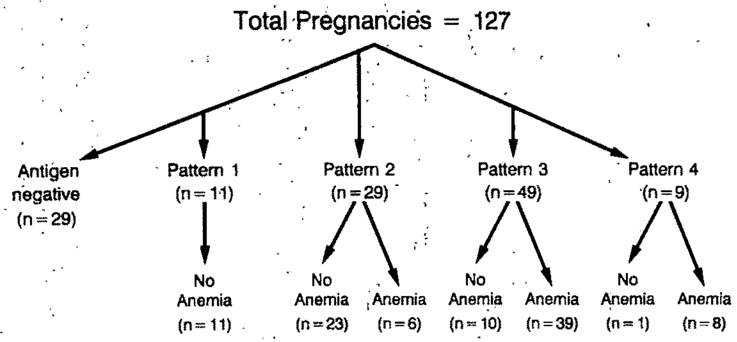

Fig. 2. Distribution of fetuses by hematologic pattern and development of severe anemia (hematocrit value <30%).

Table V. Criteria for repeat cordocentesis if affected fetus

Pattern	*Hematocrit*	*Reticulocytes*	*+ / − Direct Coombs' test result*	*Interval for cordocentesis (wk)*	*Interval for scan (wk)*	*Comments*
1	Normal	Normal	−/trace	—	4	Repeat if initial maternal indirect Coombs' test result < 128 and twofold increase documented
2	Normal	Normal or <2.5th percentile	1+/2+	5-6	2	Do not repeat after 32 wk if unchanged; delivery at term
3	Normal	>97.5th percentile	3+/4+	2	1	Continue through 34 wk if hematocrit value stable; deliver at 37-38 wk if not transfused
4	<2.5th percentile but >30%	Any	Any	1-2	1	Repeat as long as hematocrit criteria fulfilled; deliver with pulmonary maturity if not transfused

with either a reticulocyte count above the 97.5th percentile or a strongly positive direct Coombs' test result (pattern 3). Ninety-six percent of fetuses who developed or who were initially seen with anemia in the second trimester had either pattern 3 or 4. Their risk was reflected in the frequency of repeat sampling.

In spite of the high specificity of fetal blood testing, it is clear that the fetal response to alloimmunization was not completely defined by the direct Coombs' test result and the reticulocyte count. For example, three fetuses (one each with patterns 2 through 4) responded to the disease in the third trimester with an increased reticulocyte count. They ultimately were delivered at term with both a normal hematocrit value and reticulocyte count. These observations stress the importance of not initiating transfusion therapy just because the hematocrit value has fallen below the 2.5th percentile. Further, these tests do not predict postnatal hyperbilirubinemia. The fetus with pattern 4 who did not have severe anemia required two double-volume exchange transfusions for postnatal hyperbilirubinemia. It is possible that the addition of other parameters, such as fetal serum bilirubin concentration, might further refine the predictive value of the patterns and extend it into the postnatal period.

The positive predictive value of the reticulocyte count for severe disease observed here differs from that reported by Nicolaides et al,[18] who studied 29 pregnancies. These authors did not find the reticulocyte count to be of value in predicting the severity of fetal hemolytic disease. The difference in conclusions may reflect a different referral pattern, smaller sample size, reliance on smooth percentiles derived from regression with a parameter not tightly reflective of gestational age, or reticulocyte counts not corrected for gestational age.

Our data suggest that cordocentesis is an acceptable alternative to serial ΔOD_{450} measurements. Moreover, it offers several advantages. Amniotic fluid studies require a minimum of two specimens to establish a trend and lack specificity in identifying the fetus with severe anemia.[3,12,13] In contrast, only half of the pregnancies monitored by fetal blood sampling required more than two diagnostic procedures. Because the ambiguity of using the ΔOD_{450} as a predictor of fetal anemia was eliminated, women whose fetuses were not anemic could be delivered at term when the postnatal hyperbilirubinemia was more readily handled and better tolerated by the neonate and more easily treated.

Although the ΔOD_{450} reflects the concentration of a hemoglobin breakdown product, its utility is based on its relationship to the hematocrit value.[1,3,13] In the absence of anemia, severe fetal pathologic sequelae to alloimmunization are not seen. We did not randomly compare the two systems of diagnosis because our initial experience[13] with such a comparison and the larger experience of Nicolaides et al.[12] indicated that the relationship between hematocrit value and ΔOD_{450} was inexact. In agreement, Frigoletto et al.[19] observed that 37% of fetuses with ΔOD_{450} in zone III had hematocrit values >30% at birth.

One concern about cordocentesis is that it may enhance maternal sensitization more than amniocentesis. However, the anterior placenta can usually be avoided with cordocentesis as well as it can be with amniocentesis. Moreover, we have no evidence that cordocentesis performed with a needle guide to prevent lateral movement intensifies maternal sensitization to a greater degree than simple amniocentesis. The increase in maternal serum α-fetoprotein after cordocentesis in our unit is not different from the increase reported after amniocentesis.[20] Only one patient in this series who began with an indirect Coombs' test result <128 at the outset had a two-tube rise in titer. Although we did not routinely measure the maternal indirect Coombs' titer serially when it was >128 on referral, increases probably occurred as they do after amniocentesis.

Another concern is the greater risk associated with cordocentesis compared with ultrasonography-guided amniocentesis. In our experience with >800 cordocenteses, there has yet to be a procedure-related death of an appropriately grown fetus. Morbidity can occur. In this series, one fetus was delivered prematurely because of associated prolonged bradycardia. In our experience bradycardia is the major risk of cordocentesis.[16] If bradycardia could be prevented or effectively treated, we believe the risks from amniocentesis and cordocentesis would be indistinguishable if performed by an experienced operator. At this time it is unsettled as to whether the reduction in the number of invasive procedures clearly achieved by the enhanced specificity of fetal blood sampling compensates for any increased risk per procedure. It appears reasonable for the primary physician to begin the evaluation with amniocentesis (assuming a low likelihood of paternal heterozygosity and no history of a severely affected fetus) and then to refer the patient to an appropriate center for cordocentesis if the ΔOD_{450} is in zone II or higher.

Cordocentesis and intravascular transfusion are deceptively simple. In reality, they require an experienced team and a laboratory capable of performing a variety of tests on a small volume of specimen. Our series was drawn from a delivery base approaching 60,000 per year. It is not practical from the standpoint of personnel, costs, and experience for every hospital to offer a similar service. These facilities must be regionalized to maximize both safety and efficacy.

Evaluation of fetal hemolytic disease with a blood sample permits identification of the fetus at high risk of having anemia.

Steroid therapy for hydrops associated with antibody-mediated congenital heart block

William J. Watson, MD, and Vern L. Katz, MD
Chapel Hill, North Carolina

Evaluation of fetal bradycardia noted during a routine prenatal visit at 24 weeks' gestation in a mother without symptoms showed an antibody-mediated heart block with anti-La (SSB) antibody present. The fetus had a pericardial effusion and ascites. After maternal steroid therapy, the ascites resolved and the pericardial effusion was substantially diminished. Steroid therapy may be a helpful adjunct for treatment of a premature infant with hydrops as a result of antibody-mediated heart block. (AM J OBSTET GYNECOL 1991;165:553-4.)

Key words: Heart block, SSA, SSB, antibodies, steroid therapy

Complete congenital heart block associated with maternal anti-SSA or SSB antibodies may occasionally cause hydrops fetalis. The hydrops has been thought to occur as a result of low fetal cardiac output. We report a fetus with antibody-mediated heart block in whom maternal steroid therapy was associated with reversal of ascites and improvement of the pericardial effusion.

Case report

A 36-year-old primigravid patient was first seen at 15 weeks' gestation, at which time ultrasonography showed normal fetal anatomy. Amniocentesis done for maternal age showed 46,XX. At 24 weeks' gestation, during a routine prenatal visit, the fetal heart rate on auscultation was 60 beats per minute. Ultrasonography showed biometry consistent with dates, bradycardia with a rate of 58 beats per minute, a moderate pericardial effusion, and minimal ascites. Detailed views of the fetal heart did not reveal structural anomalies.

The mother was without symptoms and without a history of connective tissue disease. She was found to have a positive antinuclear antibody at 1:640 and positive anti-La (SSB) antibody with a titer of 1:128. Anti-SSA antibody was not present. Steroid therapy was discussed, and she was treated with betamethasone 12.5 mg intramuscularly daily for 2 days, followed by 60 mg of prednisone daily. After 1 week, repeat ultrasonography showed no ascites and a decreased pericardial effusion, although the fetal heart rate was unchanged. The prednisone was empirically tapered every 2 weeks; at 32 weeks' gestation she was taking 10 mg daily. The fetal pericardial effusion became minimal but did not entirely resolve. No fetal growth was seen between 33 and 35 weeks' gestation by ultrasonography, and the

patient was delivered of an infant by cesarean section at 35 weeks.

The infant weighed 2200 gm, had Apgar scores of 8 and 8 at 1 and 5 minutes, respectively, and did well without cardiac pacing. An electrocardiogram showed third-degree atrioventricular block, and the rate varied from 52 to 75 beats per minute. At 5 weeks of age mild congestive heart failure developed with a heart rate in the low 50s; a pacemaker was placed. The infant is doing well at 6 months of age.

Comment

Hydrops that develops in a fetus with antibody-mediated heart block has traditionally been thought to be caused by low-output cardiac failure. Recently, however, an immune mechanism has been proposed for these serous effusions, and two fetuses have been treated in utero with steroid therapy, with improvement of the fetal condition.[1, 2]

Immune-mediated hydrops may be caused by inflammation of the fetal peritoneum and pericardium. Steroid therapy in such cases may decrease this inflammation. Because prednisone does not cross the placenta in substantial amounts, it may work by decreasing maternal antibody levels.

Although one must be cautious in attributing the resolution of hydrops to steroids, the temporal association between therapy and fetal improvement in this and two other reported cases[1, 2] is suggestive. The dosage and duration of therapy in this case was empiric, and it is unclear whether the use of two different steroids (betamethasone and prednisone) is indicated. We based our therapy on the report of Richards et al.[2] who used both steroids in a similar clinical situation.

Maternal steroid therapy may be a useful in utero therapy for the premature fetus with antibody-mediated congenital heart block in which hydrops develops.

Prognostic factors and complication rates for cervical cerclage: A review of 482 cases

Marjorie C. Treadwell, MD, Richard A. Bronsteen, MD, and Sidney F. Bottoms, MD
Detroit, Michigan

Charts from 482 singleton pregnancies undergoing cerclage placement in patients over a 6-year period were reviewed. Cervical dilatation at time of surgery, number of previous spontaneous losses, and gestational age at placement were key determinants of outcome. The most frequent complication, premature rupture of the membranes, ultimately occurred in 38% of patients. The 6.6% infection rate was increased in patients undergoing emergent versus elective surgery (12.7% vs 4.7%, $p < 0.005$) and in patients at increased dilatation at time of surgery (5.7% for ≤2 cm vs 41.7% for >2 cm, $p < 0.005$). McDonald and Shirodkar procedures had similar obstetric outcomes in patients undergoing their first cerclage. The subgroup of patients with prior cerclage surgery showed improved birth weight when the Shirodkar procedure was performed instead of the McDonald cerclage (mean birth weight 3020 vs 2470 gm, $p < 0.005$). An increased rate of primary cesarean section was found in the Shirodkar group (31% vs 17%, $p < 0.005$). Complication rates and pregnancy outcome appear to reflect cervical dilatation more than gestational age at time of surgery. (AM J OBSTET GYNECOL 1991;165:555-8.)

Key words: Cerclage, incompetent cervix

Cervical cerclage has become an established treatment for cervical incompetence. It is often unclear in individual cases whether the benefits of the procedure outweigh its potential complications. There is also continued disagreement regarding choice of surgical technique.

The role of cerclage placement with advanced gestation or dilatation remains controversial. Schwartz et al.[1] described 74 cases of cervical cerclage with relatively low rates of cervical laceration cesarean section and no significant difference in infection rates between early and late cerclage placement (after 18 weeks' gestation). Charles and Edwards[2] reported a 2.6-fold increase in incidence of chorioamnionitis and a threefold increase in premature rupture of membranes (PROM) before 32 weeks' gestation when the procedure was performed after 18 weeks. They concluded that the optimum time of placement was between 14 and 18 weeks' gestation. Other series have noted an increased frequency of abdominal delivery,[3] high overall rates of PROM,[4, 5] and high rates of chorioamnionitis[5, 6] complicating all pregnancies managed with cerclage. A marked increase in cervical laceration rate (23.8%) has been noted among patients undergoing emergency procedures.[3] Although it has been reported in small series that advanced cervical dilatation (>3 cm) is associated with a worse prognosis,[7, 8] this factor is not considered in most studies. Some authors have advocated cerclage placement for patients with bulging membranes before 25 weeks gestation.[9, 10]

Surgical technique, as well as patient selection, remains controversial. In Harger's[11] review of 251 cases, McDonald and Shirodkar procedures had equivalent success rates and morbidity. This finding was confirmed by Cardwell[12] in a study of 129 pregnancies. In spite of this, many obstetricians routinely advocate one technique in preference to the other.

Previous studies have been limited by the number of cases, collection over excessively long periods of time, or not considering one or more important prognostic factors. Prospective, randomized studies examining cerclage have excluded patients with cervical dilatation, shortening, or previous clerclage.[4] There is wide acceptance of cervical cerclage placement for treatment of the incompetent cervix. Withholding cerclage therapy with documented cervical incompetence may be considered unethical, making completely randomized studies impossible. Consequently, the relationships between gestational age, dilatation, and type of procedure to eventual results remain unclear. The purpose of this study is to perform a comprehensive evaluation of the determinants of outcome for cerclage placement. It is hoped that this information will assist in selection of patients and surgical technique.

Material and methods

We reviewed medical records of 437 patients having one or more cerclage procedures during singleton

24-26	17	11.8 ± 4.4	36.8 ± 4.3

pregnancies between January 1982 through December 1987 at our hospitals. Surgeries performed at gestational ages <12 weeks or <26 weeks were not included in the analysis because they were believed to reflect unacceptable variation in the quality of care. On the remaining 482 procedures maternal age, gravidity, parity, previous spontaneous losses at <24 weeks' gestation and history of previous cerclage placement were abstracted. The gestational age of cerclage placement and type of cerclage procedure (Shirodkar vs McDonald) were determined. Indications were classified as elective when based on past obstetric history or emergent when cervical changed prompted operation. Cervical dilatation at the time of the procedure was recorded in the latter group. Outcome variables included gestational age at delivery, birth weight, PROM, and clinical chorioamnionitis (temperature >38° C and uterine tenderness). Other data included the mode of delivery and complications such as cervical lacerations. Unfortunately, information regarding neonatal morbidity and mortality is not available on these specific pregnancies. About 60% of patients at our hospitals have private attending physicians and the remainder are assigned to staff in the department. Resident physicians under attending supervision perform most cerclage procedures on both private and staff services. A variety of suture material were used secondary to the large number of practitioners. Almost always a single stitch was placed; tocolytic and antibiotic prophylaxis were not routinely used.

Gestational age at delivery and the interval from cerclage placement to delivery were analyzed with stepwise multiple regression. The Student *t* test was used to evaluate continuous variables such as birth weight differences between two groups. Discriminant function analysis was used to evaluate factors associated with PROM, a dicotomous outcome. Other nominal variables such as chorioamnionitis were analyzed with χ^2. To adjust for the multiple comparisons made in this study, $p < 0.005$ was considered significant.

Results

Characteristics of the pregnancies are presented in Table I. The relatively older maternal age appears to reflect the incidence of reproductive problems documented by a median number of spontaneous abortions exceeding the median parity. It should be noted, however, that the number of previous spontaneous abortions indicates that many patients had none or only one previous loss at the time of cerclage placement. The mean gestational age at placement was 17 weeks. Of the 482 procedures, 364 were elective; the remainder had documented cervical change. Cervical dilatation at time of placement in the latter group ranged from 0 to 4 cm.

The mean interval to delivery was 17.7 weeks with a range of 0 to 30 weeks; the mean gestational age at delivery was 34.8 weeks with a range of 12 to 43 weeks. Tables II and III are descriptive tables that show an interesting contrast between dilatation and gestational age at cerclage placement as they relate to gestational age at birth and interval to delivery. Advanced dilatation was associated with increasing prematurity and decreased interval to delivery. Among those with no dilatation at time of cerclage, earlier gestational age at placement resulted in longer intervals to delivery, as would be anticipated. In these procedures an increasing mean gestational age at delivery was noted with advancing gestational age at time of cerclage. It should be noted placement late in gestation excluded cases that aborted early in pregnancy. The results of the stepwise multiple regression analysis of this data are summarized in Table IV. Cervical dilatation at time of cerclage, gestational age at placement, and number of previous pregnancy losses at <24 weeks' gestation were key de-

Table IV. Results of stepwise multiple regressions relating prognostic factors of obstetric outcomes

Shirodkar cerclage	33.3%	0.01	NS
Indication (elective)	36.3%	0.59	NS

terminants of pregnancy outcome. Prior cerclage placement, type of cerclage, indication, gravidity, and parity did not appear to be significant after accounting for these factors.

The most frequent complication noted was PROM, ultimately occurring in 38.2% of pregnancies. The analysis summarized in Table V suggests that dilatation at cerclage placement may be the most important factor relating to incidence of PROM. When dilatation was removed from the analysis no other factors appeared to have a significant impact on PROM rates. In 116 of the 184 patients with PROM delivery occurred at <37 weeks' gestation; 48 were delivered of infants at <27 weeks. The infection rate (6.6% overall) differed according to cervical dilatation [28/451 (6.2%) for ≤2 cm vs 5/12 (41.7%) for >2 cm, $p < 0.005$] and indication for procedure [emergent 17/118 (14.4%) vs elective 19/364 (5.2%), $p < 0.005$].

The incidence of cervical lacerations for emergent procedures was not significantly different from that of elective procedures. Although there was a trend for cervical lacerations to be more common in patients who underwent cerclage placement after 18 weeks' gestation, it was not statistically significant [15/140 (10.7%) vs 16/342 (4.7%) $p < 0.02$]. Cervical fistulae in three patients developed after cerclage placement.

McDonald procedures were performed in 377 pregnancies; Shirodkar technique was used for the other 105 cases. All patients dilated >1 cm at the time of operation underwent McDonald cerclages. All the McDonald sutures were removed before or at the time of presentation to labor and delivery. Four patients with a Shirodkar cerclage underwent primary cesarean sections with no attempt at cerclage removal (one patient required removal after delivery because of infection at the cerclage site). Attempts were made to remove the remainder of the Shirodkar sutures before delivery. The overall cesarean rate in this series was 31.8%. The primary cesarean rate was 31% with Shirodkar cerclage compared with 17% for McDonald technique ($p < 0.005$). This was attributable to cesarean deliveries performed for cervical dystocia in 12/105 cases with Shirodkar cerclages compared with 10/377 in the McDonald group ($p < 0.005$). Rates of primary cesarean sections performed for other indications and repeat cesarean sections were similar for the two cerclage procedures. There were 182 patients undergoing repeat cerclage procedures. Within this subgroup, pregnancies managed with Shirodkar cerclage instead of McDonald procedure appeared to have improved mean birth weight (grams) (3020 ± 951 vs 2470 ± 1100, $p < 0.005$) and gestational age at delivery (weeks) (37.0 ± 5.6 vs 34.5 ± 6.5, $p < 0.03$).

Comment

Interpretation of these findings have led us to several conclusions. The most important determinants of gestational age and interval to delivery appeared to be cervical dilatation at the time of procedure, gestational age at placement, and the number of previous losses. Cervical dilatation >2 cm at cerclage was associated with more severe prematurity and a greater risk of PROM, but no increase in the frequency of cervical lacerations. Shirodkar technique resulted in an increased primary cesarean section rate. Although there was no demonstrable advantage over the McDonald procedure in patients undergoing their initial cerclage surgery, patients with previous cerclage appeared to have improved birth weights when Shirodkar technique was used.

Improved pregnancy outcomes with cerclage placement before 18 to 20 weeks' gestation,[2, 5, 11, 12] and a twofold to three-fold increase in PROM and chorioamnionitis with placement after 18 weeks have been reported.[2] These considerations have been part of the rationale for advocating surgery between 14 and 18 weeks' gestation. Our increased rate of PROM (38%) appeared related to the large number of emergency placements in the face of cervical dilatation; advancing gestational age did not have as strong an influence.

Our 6.7% incidence of cervical lacerations is consistent with previous literature.[1, 3, 11, 13, 14] Contrary to previous reports, emergent procedures were not at increased risk and dilatation or history of prior cerclage did not appear to be factors.

Increased cesarean rates have been noted in most cerclage series,[3, 4, 13-15] particularly among patients with Shirodkar procedures.[11] Our current results confirm in a larger series that this pattern has continued. Much of the use of abdominal delivery can be directly attributed to the cerclage procedure. In addition to the practice of performing primary elective cesarean on patients with a Shirodkar cerclage in place, there is an increased incidence of cervical dystocia.[1, 6, 11, 16] The rate of cervical dystocia was 2.6% in patients with a McDonald cerclage and 11.4% with the Shirodkar procedure. This rate of cervical dystocia (4.3% overall) rose to 14.0% (12/86) in patients with a Shirodkar cerclage who were given a trial of labor. On the basis of this finding, we believe that use of modified Shirodkar technique with removal during labor may cause more scarring of the cervix, leading to a greater risk of cervical dystocia and cesarean section. With the exception of cesarean rates, numerous series have reported similar obstetric outcome with McDonald and Shirodkar procedures.[3, 7, 9, 12] We found this to be true only in patients with no history of prior cerclage.

We would like to emphasize the limitations inherent to this and all other retrospective studies. A prospective randomized trial is needed to make definitive conclusions regarding the advisability of cerclage in cases in which the benefits and risks appear to be closely balanced. A similar study is needed to determine the optimal surgical technique. Nonetheless, we believe these findings have several implications for clinical practice and for future research.

When considering cerclage, gestational age appears to be a less important factor than cervical dilatation. Certainly, patients and their physicians should be aware of the poor prognosis after emergency placement in a dilated cervix; the risks may outweigh the benefits in many cases. The belief that modified Shirodkar technique with removal of the cerclage is comparable to the McDonald procedure appears to be mistaken; the need for abdominal delivery is still increased because of a greater likelihood of cervical dystocia. The role of placement of a permanent Shirodkar cerclage at time of initial cerclage surgery was not examined. Certainly, if the plan is for modified Shirodkar cerclage with removal at delivery we advocate the McDonald procedure as the initial cerclage procedure when possible to avoid the morbidity and mortality associated with cesarean delivery. In patients undergoing repeat cerclage the Shirodkar appears to offer improved birth weights and higher gestational age at delivery. It may be warranted to use this technique more frequently in this subgroup of patients.

Incidental appendectomy during videolaseroscopy

Camran Nezhat, MD, and Farr Nezhat, MD
Atlanta, Georgia

One hundred incidental appendectomies were performed in patients undergoing operative laparoscopy (videolaseroscopy) for evaluating and treating various major diseases of the reproductive organs. Except for a fever resolving within 24 hours in one case and mild periumbilical ecchymosis, there were no intraoperative or postoperative complications. All patients were discharged within 24 hours of surgery. Average hospital stay was 14 hours. All cases have been followed up for a minimum of 8 months. We believe any risk associated with elective appendectomy as reported here is minimal and outweighed by the benefits of eliminating future emergency appendectomy, simplifying future differential diagnosis of pelvic pain and removing unsuspected abnormality found in the appendix. (AM J OBSTET GYNECOL 1991;165: 559-64.)

Key words: Incidental appendectomy, videolaseroscopic appendectomy, pathology in elective appendectomy, endometriosis, laparoscopy, operative laparoscopy

Although elective, prophylactic, or incidental appendectomy during surgery for treating other abdominal pathologic conditions is not a settled issue,[1] many physicians, particularly in obstetrics and gynecology, advocate the practice with some qualifications and unless there are specific contraindications.[2-4] The emergence of diagnostic and operative laparoscopy as a viable option to laparotomy over the past two decades[5-14] has followed development of safe procedures for using instruments and tools, wedding endoscopy with electrocautery and using laser and video technology.[8, 12-14] Appropriate applications have involved a variety of gynecologic disorders and procedures, including incidental appendectomy. We review here the results of 100 consecutive appendectomies performed during videolaseroscopy in which diseases of the reproductive organs were being evaluated and treated.

Material and methods

One hundred patients undergoing videolaseroscopy with the carbon dioxide laser for evaluation and treatment of endometriosis with diverse pelvic pathologic conditions were studied. Among them were 14 who requested appendectomy before they gave informed consent. Patients' ages ranged from 17 to 45 years. Fifteen were <25 years old; 53 were between 25 and 35; and 32 were >35 years old. General endotracheal anesthesia was used in all cases, and each patient received a 2.0 gm intravenous prophylactic dose of cefoxitin sodium (Mefoxin; Merck Sharp and Dohme, West Point, Pa.) or 100 mg of Vibramycin (Pfizer, New York).

Current procedures[8-14] evolved from efforts initiated in 1983 using video-augmented instrumentation at hand to develop optimal techniques for laparoscopic surgery, including appendectomy (Fig. 1). Those employed in the present study involved routine induction of pneumoperitoneum and insertion of the laparoscope intraumbilically. Subsequently three 5.0 mm suprapubic punctures were made: one in the lower right quadrant, one in the lower left quadrant, and one in the midline, two fingerbreadths above the pubic symphysis. These trocar punctures allowed the introduction of ancillary instruments such as grasping forceps, endoloop suture applicators, and units for suction and irrigation and bipolar electrocautery. Hemostasis was accomplished with the laser beam or by electrocautery.[8-10]

Gynecologic procedures taking from 30 minutes to 3 hours were performed. Initial evaluation revealed 58 cases of pelvic endometriosis; 10 others had pelvic adhesions, and 32 had endometriosis and adhesions of the pelvis and abdomen, including severe involvement of the descending colon and rectovaginal septum. Major surgery included carbon dioxide laser ablation or excision of peritoneal and ovarian endometriosis, ovarian cystectomy, salpingoovariolysis, salpingectomy,[10a] salpingo-oophorectomy, salpingoneostomy, adnexectomy, myomectomy, enterolysis, ureterolysis, ureteroneocystostomy, and partial colon resection for the treatment of endometriosis.[10b]

On completion of thorough treatment of the pelvic pathologic condition, preparation for appendectomy included inserting grasping forceps through the lower right-quadrant trocar sleeve and passing the bipolar electrocoagulator and the suction irrigator through the midline and lower left-quadrant punctures, respec-

tively. Then, with the video laparoscope system in the umbilical channel, the appendix was located. Subsequently, a direct lens-laser coupler was attached,[9-12] and the carbon dioxide laser beam through the operating channel of the laparoscope (Fig. 1) was used as a long scalpel and to coagulate small blood vessels. The appendix was mobilized and examined after lysis of periappendiceal or pericecal adhesions as necessary. This was done carefully in case there was attachment to the lateral pelvic wall or retrocecal appendix. Next, the bipolar cautery and the carbon dioxide laser were used sequentially to coagulate and cut the mesoappendix, ½ centimeter away from the ileocecal area.

At this point the bipolar coagulator was withdrawn and the endoloop applicator was inserted through the suprapubic midline puncture. Two chromic endoloop sutures (Ethicon, Somerville, N.J.) were passed to the base of the appendix, 3 to 5 mm from the cecum, and then tied one on top of the other. Both suture ends were cut with the carbon dioxide laser. A third endoloop suture was applied, 1 cm distal to the other sutures, and then cut long, leaving a 15 cm tail to facilitate retrieval should the appendix inadvertently fall into the pelvic well. With the carbon dioxide laser the appendix was cut between the sutures mentioned (Figs. 2 to 5). Luminal portions of the appendiceal stump and the

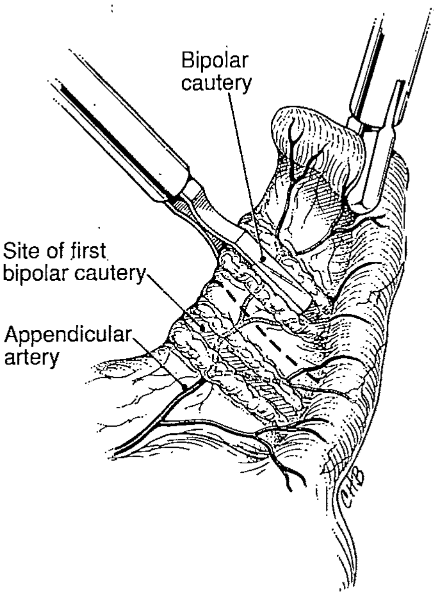

Fig. 2. Mesoappendix being coagulated.

removed appendix were seared with the carbon dioxide laser and rinsed with one or two drops of povidone-iodine (Betadine, Purdue Frederick, Norwalk, Conn.) (Fig. 6). The tissues were then copiously irrigated with lactated Ringer's solution containing heparin, 5000 U/L.

The appendix, which was subsequently sent to the laboratory, was removed from the abdomen either by use of a long, grasping forceps passed through the operating channel of the laparoscope or suprapubically with the short grasper; if appropriate, an appendix extractor was used through the sleeve of a 10 mm trocar, replacing the central 5 mm one. Instruments, possibly contaminated, were removed from the surgical area. No adjunctive therapy was added to the pelvic cavity. Last, the appendiceal and other operative sites were inspected for hemostasis by completely emptying and reinsufflating the carbon dioxide gas into the abdominal cavity and finally irrigating with lactated Ringer's solution.

Appendectomies were accomplished in from 4 to 21 minutes. Postoperative instructions included avoiding solid food for 24 hours; otherwise, instructions were those routinely used for gynecologic procedures, including an outpatient evaluation the day after surgery.

Results

No major intraoperative complications occurred in any patient. All patients were discharged from the hospital within 24 hours of surgery. Seven remained overnight because of patient preference or surgery late in the day. The average hospital stay was 14 hours.

In one patient a temperature of 101° F developed the evening after surgery and she was observed overnight. No acute abdominal signs occurred, and the abdomen was soft the next day. White blood cell count was 7500/mm^3, with no shift in the differential. The temperature fell, and the patient was discharged from the hospital free of fever.

All patients resumed a regular diet the day after surgery. Except for mild periumbilical ecchymosis, no apparent postoperative complications have occurred in the study group. All have thus far been followed up for a minimum of 8 months.

Fifty-two of the 100 removed appendixes were reported as normal. These include 12 instances of focal fibrous obliteration of the lumen of the appendix and 14 patients requesting appendectomy, as noted earlier. Pathologic findings encompassed 28 appendixes with adhesions, 14 with endometriosis, four with focal collections of chronic inflammatory cells and hemosiderin-laden macrophages on the external surface, one benign mucocele, and one carcinoid.

Comment

The lack of complications after incidental appendectomy, as reported in this series and not noted elsewhere, prompts us to recommend laparoscopic appendectomy in qualified hands, an opinion shared by others with similar case experiences. Schreiber,[15] for example, in 1987 reported 151 cases of laparoscopic incidental appendectomy with only one complication, an endocoagulative injury to the cecum that was successfully repaired by subsequent laparotomy. Schreiber, who essentially followed the procedures of Semm[16] except for not "countersinking" the appendiceal stump, considered laparoscopic appendectomy " a worthwhile alternative to classical appendectomy, even in acute appendicitis." Average hospitalization was 8.1 days (range, 4 to 22 days), and the author emphasized the subjective well-being of patients.

Gotz et al.[17] recently reported efforts initiated in May 1989 to make laparoscopic appendectomy for acute or chronic appendicitis a routine tool of the general surgeon. They simplified procedures espoused by Semm,[16] including not invaginating the appendiceal stump, and adopted video monitoring as used and promulgated by Nezhat.[12, 13] On the basis of 388 patients with a variety of acute and chronic vermix disease, they concluded that laparoscopic appendectomy is "a practicable and reasonable alternative to routine surgery." Complications, all successfully treated by subsequent laparotomy and mostly occurring early in the series, prompted the authors to emphasize that there was a significant learning curve and that 1½ years of training was required for proficiency in the procedures. Average hospitalization was 1 week. Most patients resumed a normal diet the day after surgery. Complaints of postoperative ab-

dominal pain were seldom made, and the authors regarded this as "certainly responsible for the early mobilization of most patients."

Unlike Semm,[16] we do not bury the appendiceal stump, thus avoiding the risk of invading the lumen of the bowel with a needle. Relevant is a prospective randomized trial reported in 1985 by Engstrom and Fenyo[18] involving 735 consecutive appendectomies in which stump invagination was compared with simple ligation. The authors recommended the latter as the procedure of choice. Also, we do not, as advocated by Semm,[16] ligate the appendiceal artery but rely on bipolar cautery for coagulating the appendiceal artery and mesoappendix. The major difference between our technique and procedures followed by authors previously cited is the use of the carbon dioxide laser for cutting and location of the ancillary trocars.

It is relevant to note here that there is, for reasons not entirely clear, more than a tenfold variation in the published pathology rates associated with incidental appendectomy. Ikard[19] in 1987, for example, in a prospective randomized study to determine infection rates in 100 patients undergoing cholecystectomy, 47 of whom also had incidental appendectomy, found appendiceal pathologic conditions in only 6% of cases. In contrast, in 1983 von Rechenberg[20] reported abnormal appendixes in 82.9% of 113 incidental appendectomies among 627 gynecologic laparotomies. Also, among 5369 gynecologic laparotomies studied by Krone and Sperke,[21] 1718 preventive appendectomies were done; 368 appendixes (21.4%) were normal, 136 (7.9%) revealed acute appendicitis, and 1118 cases (65.1%) showed chronic disease, including an unspecified number with fibroid scarring and total obliteration. The remaining 96 cases (5.6%) showed carcinoid, mucocele, and endometriosis. Interestingly, a report by Westermann et al.[22] in 1986, from a teaching service where

routine appendectomy during extensive gynecologic surgery was the rule, noted histologic abnormalities in 28.7% (68) of 233 cases. The authors chose to view luminal fibrosis, peri-appendicitis (acute and chronic), chronic inflammation, mucosal hyperplasia, and a foreign body reaction found in 33 cases (14.0%) as equivocal or variations of normal but regarded 34 (14.6%) as pathologic. The latter included metastatic carcinoma of the endometrium and ovaries, endometriosis, carcinoma of the cecum, carcinoid, mucocele, and tuberculosis. The authors did, however, note that what fraction of appendiceal abnormalities should be viewed as definitely pathologic was a controversial and unresolved issue.

In view of the reported variables of patient selection and preference, preoperative diagnosis,the character of the surgery, pathologic terminology, age, sex, and sample size, it would hardly be possible to predict appendiceal findings in the group of patients in the current study. All were known to have endometriosis and all were referred to the endometriosis clinic for endoscopic surgery. Our findings of normal appendixes in only half of the cases adds an additional dimension to the literature on incidental appendectomy.

Regarding risk versus benefit, four prospective randomized studies noted that appendectomy, whether termed *elective, incidental, in passing, preventive,* or *prophylactic,* did not significantly alter patient response to major laparotomies. Two sereis concerned cholecystectomy with and without appendectomy.[19-23]

The outcome of elective cesarean section was not significantly influenced by adding appendectomy.[24] Appendectomy was randomly added in patients without intraabdominal injury undergoing exploratory laparotomy for penetrating abdominal trauma.[25] This report viewed incidental appendectomy as a relatively innocuous procedure in trauma patients. These authors view elective or incidental appendectomy as a safe procedure, having minimal risks when appropriately added to major surgery by laparotomy. Their results reinforced our conviction that elective appendectomy as reported in this study adds minimal risk.

Whatever small risk there might be, including that attributable to anesthesia, is far outweighed by benefits gained: first, from eliminating appendectomies as a future hazard, particularly in women of reproductive age; second, from simplifying differential diagnosis involving subsequent, acute intraabdominal and pelvic emergencies; third, from removing pathologic appendixes that escaped prior diagnosis.

In summary, 100 incidental appendectomies, performed during operative laparoscopies carried out to evaluate and treat endometriosis with various gynecologic disorders, added from 4 to 21 minutes to the procedures. Except in one patient with transient fever (101° F), which resolved within 24 hours, and mild periumbilical ecchymosis, there were no intraoperative or postoperative complications of note. All of the patients left the hospital within 24 hours of surgery. Average hospital stay was 14 hours.

Follow-up of all patients for a minimum of 8 months revealed no apparent morbidity or change in recovery time attributable to appendectomy.

The risks are minimal and are outweighed by the benefits of eliminating future emergency appendectomies, simplifying differential diagnoses of pelvic pain, and removing appendiceal abnormality.

We conclude that in the hands of experienced endoscopists, incidental prophylactic or elective appendectomy can be performed safely by videolaseroscopy.

Use of hydroxyurea in chronic myeloid leukemia during pregnancy: A case report

M. Patel, MB, ChB, MMed(Wits),[a] I.A.F. Dukes, MB, ChB,[b] and J.C. Hull, MB, ChB[c]
Johannesburg, South Africa

The concomitant occurrence of pregnancy and chronic myeloid leukemia is uncommon. The use of hydroxyurea in chronic myeloid leukemia during pregnancy is unknown. We report on a patient with chronic myeloid leukemia in whom hydroxyurea was used during pregnancy with a successful outcome for both mother and fetus. (Am J Obstet Gynecol 1991;165:565-6.)

Key words: Chronic myeloid leukemia, pregnancy, hydroxyurea

Various modalities of treatment have been used in the management of chronic myeloid leukemia during pregnancy, including the use of cytotoxic drugs, splenic irradiation (with shielding of the uterus), and, more recently, leukapheresis.

Hydroxyurea, a cytotoxic agent that inhibits dexoyribonucleic acid synthesis, is useful in both the chronic and the accelerated phases of the course of chronic myeloid leukemia. Its role in the pregnant patient has not been elucidated. In this case report we describe the successful management with hydroxyurea in a case of chronic myeloid leukemia throughout the patient's pregnancy.

Case report

A 33-year-old woman (gravida 3, para 1) with chronic myeloid leukemia was 12 to 14 weeks pregnant at routine follow-up examination. She had two previous pregnancies. The first resulted in a normal vaginal delivery 12 years previously, and the second ended in a miscarriage at about the fourth month of pregnancy, 8 years previously. Chronic myeloid leukemia was diagnosed 7 months previously. On initial examination, she had evidence of mild pallor, splenomegaly (3 cm), and hepatomegaly (2 cm). The white blood cell count was 146 × 10^9/L with 72% neutrophils, 1% promyelocytes, 9% myelocytes, 8% metamyelocytes, 6% lymphocytes, 1% monocytes, and 3% basophils. The hemoglobin level was 11.4 gm/dl and the platelet count was 284 × 10^9/L. Results of the Philadelphia chromosome test were positive.

The pregnancy was discovered at the end of the first trimester, and at that time she was being treated with hydroxyurea. Therefore the drug was continued throughout the pregnancy. A dose ranging between 500 mg and 1 gm orally daily was used (during the pregnancy). The patient's course from diagnosis until death is depicted in Fig. 1. At 36 weeks' gestation she went into spontaneous labor and had a vaginal delivery of a normal, physically healthy 2670 gm male infant with normal blood counts. There were no perinatal complications.

The mother remained well for 16 months after delivery but died 2 months later, after acceleration of the disease. At present, the baby is 26 months old, is physically and developmentally normal, and has a hemoglobin level of 11.9 gm/dl, a white blood cell count of 7.12 × 10^9/L, and a platelet count of 336 × 10^9/L.

Comment

The association of chronic myeloid leukemia and pregnancy is infrequent. The successful management of chronic myeloid leukemia during pregnancy revolves around the need to treat the mother appropriately to ensure and maintain maternal well-being and the desire to avoid fetal compromise, especially in the first trimester of pregnancy.

To this end, accepted treatment modalities in such patients generally involve the use of cytotoxic agents, ionizing radiation, and leukapheresis.

Of the cytotoxic drugs, busulfan has been the most widely used agent with a favorable outcome in the vast majority of patients.[1] Splenic irradiation with shielding of the uterus has been used without obvious teratogenic effects. However, there are potential leukemogenic effects of in utero exposure to radiation. More recently, leukapheresis has been used successfully[2] and may be considered the treatment of choice in selected patients because of its lack of teratogenic effects. It also has the added advantage of not adversely influencing the

course of chronic myeloid leukemia and can result in improvement in symptoms. However, it is costly and time consuming and may be inconvenient for some patients. In certain centers it may not be readily available. In recent years hydroxyurea has been increasingly used in the management of patients with chronic myeloid leukemia. Its advantages are ease of administration, short duration of action, and absence of cross sensitivity with and resistance to alkylating agents. Compared with those of other cytotoxic drugs, side effects are uncommon. The role of hydroxyurea in the pregnant patient has not been elucidated.

It appears from this case report that hydroxyurea may be well tolerated and serve as a useful alternative to leukapheresis in pregnant patients with chronic myeloid leukemia, in situations where leukapheresis is not available or practicable. Further reports in this group of patients will define the precise role of hydroxyurea in chronic myeloid leukemia during pregnancy.

Aprotinin blocks the binding of pro atrial natriuretic peptides 1 to 30, 31 to 67, and 99 to 126 to human placental membranes

David L. Vesely, MD, PhD
Tampa, Florida

Two peptides with natriuretic and diuretic properties consisting of amino acids 1 to 30 and 31 to 67 of the 98 amino acid N-terminal end of the prohormone of atrial natriuretic factor, which normally circulates in humans, were investigated to determine if they have specific binding sites of placental membranes. Competitive binding experiments revealed that atrial natriuretic peptides 1 to 30, 31 to 67, and 99 to 126 (i.e., C-terminus) each had specific and separate binding sites. The dissociation constants for atrial natriuretic peptides 1 to 30, 31 to 67, and 99 to 126 binding to human placental membranes were similar at 4.3 ± 0.6 nmol/L, 3.1 ± 0.4 nmol/L, and 2.9 ± 0.5 nmol/L, respectively. Each peptide bound to the placental membranes between 10^{-8} and 10^{-11} mol/L but could bind to the other peptides' receptors only at supraphysiologic concentrations of 10^{-6} and 10^{-7} mol/L. The protease inhibitor aprotinin (50 μg/ml) blocked the binding of the atrial natriuretic peptides 1 to 30, 31 to 67, and 99 to 126 to their respective receptors. These results suggest that atrial natriuretic peptides 1 to 30 and 31 to 67 do not work through the atrial natriuretic factor receptor but rather have their own separate and distinct receptors on placental membranes and that the protease inhibitor aprotinin antagonizes their respective binding to placental membranes, suggesting that integral membrane proteases may be modulators of atrial natriuretic peptides receptor function. (AM J OBSTET GYNECOL 1991;165:567-73.)

Key words: Atrial natriuretic peptides, receptors, protease inhibition, placenta, aprotinin

Cardiac myocytes contain biologically active peptides with natriuretic, diuretic, and vasodilatory properties.[1-3] In addition to atrial natriuretic factor (ANF) the 126 amino acid ANF prohormone contains two other peptides with vasodilatory, diuretic, and natriuretic properties.[2, 3] These two peptides consisting of amino acid 1 to 30 (i.e., proANF 1 to 30 or long-acting sodium stimulator) and amino acid 31 to 67 (i.e., proANF 31 to 67 or vessel dilator) of the ANF prohormone are equally as effective as ANF (amino acid 99 to 126 of the prohormone) in their vasodilatory[2] and natriuretic and diuretic properties.[3] Recently the 98 amino acid N-terminus of the ANF prohormone containing proANF 1 to 30 and proANF 31 to 67 and the C-terminus (i.e., atrial natriuretic factor) were found to circulate in humans[4-15] and to increase in the circulation with the increase in blood volume of a normal pregnancy.[16] In addition to the whole 10,000 molecular weight N-terminus, a 4000 molecular weight peptide consistent with proANF 31 to 67 from the midportion of the N-terminus also circulates as determined by G-50 Sephadex gel permeation chromatography.[13] The fact that proANF 31 to 67 circulates normally in the plasma as a distinct peptide in addition to the whole N-terminus suggests that proANF 1 to 30 and proANF 69 to 98, which normally are attached to proANF 31 to 67 in the N-terminal polypeptide chain, also may circulate after proANF 31 to 67 has been proteolytically cleaved from the midportion of the N-terminus.[12, 13]

Atrial natriuretic factor (i.e., the C-terminus of the prohormone) binds to placental membranes where it may be involved in fluid and electrolyte homeostasis.[17-19] Since proANF 1 to 30 and 31 to 67 have diuretic and natriuretic properties that are similar to those of ANF,[3] this study was designed to determine if the proANFs 1 to 30 and 31 to 67 have separate and distinct binding sites on placental membranes. When these newly discovered peptide hormones were found to have distinct binding sites on placental membranes, this investigation was extended to determine if aprotinin, a protease inhibitor, could block their binding similar to its previously described ability to antagonize the binding of human chorionic gonadotropin to its receptor on ovarian membranes.[20]

iodine 125 (specific activity, 1100 Ci/mmol), ^{125}I-proANF 31-67 (specific activity, 1500 Ci/mmol), and ^{125}I-ANF (specific activity, 2000 Ci/mmol) were labeled by the Iodogen method[21] by Peninsula Laboratories (Belmont, Calif.). To determine the specific activity of these three ligands, 0.2 mmol/L of each peptide was conjugated with 500 µCi of sodium iodide. After purification on high-pressure liquid chromatography, the amount of radioactivity in each fraction was added together and then divided by 0.2 nmol/L to determine the specific activity of each of the respective peptides. Unlabeled human proANF 1 to 30, 31 to 67, and human ANF (amino acid 99-126) also were purchased from Peninsula Laboratories.

Purity of peptides by high-pressure liquid chromatography. Each of these peptides was tested for purity on a liquid chromatograph from Waters Associates, which was composed of a model 680 gradient controller, two model 510 high-pressure liquid chromatography pumps, a model U6K injector, a Novapak C18 (5 µm) cartridge column, and a model 481 LC spectrophotometer. Separation was achieved with a linear gradient of 0% to 60% solvent B over 40 minutes at a flow rate of 1.0 ml/min. Solvent A was 0.1% trifluoroacetic acid and water and solvent B was 0.1% trifluoroacetic acid and acetonitrile. The wavelength monitored was 210 nm. Each of the peptides used in this investigation was pure when tested in this manner.

Preparation of placental membranes. Membrane preparation of a plasma membrane fraction of placenta was by the method of Siegel et al.,[22] which we have used previously to prepare smooth membranes from vasculature.[23] Fresh placentas ($n = 6$) from normal term deliveries were washed several times with phosphate-buffered saline solution, pH 7.4, and the supporting amnion and chorion were removed. The tissue (100 to 150 gm) was finely minced, suspended in a buffer containing 5 mmol/L ethylenediaminetetraacetate, 1 mmol/L Tris hydrochloride, pH 7.4, 2 mmol/L magnesium chloride, 1 mmol/L dithiothreitol, and 0.1 mmol/L phenylmethylsulfonylfluoride at a ratio of 6 ml buffer to 1 ml minced placenta, and stored on ice for 30 minutes to allow cell lysing to occur (all further procedures are at 4° C). The cell suspension was homogenized in a Brinkman Polytron homogenizer at slow speed for 1 minute. Aliquots of 25 ml homogenate were layered over 10 ml 44.5% sucrose and 20 mmol/L Tris hydrochloride, pH 7.4, and centrifuged at 70,000 g for 30 minutes. The membrane layer floating on top of the sucrose was isolated and transferred by a pipette into an ultracentrifuge tube containing 0.25 mmol/L sucrose, 50 mmol/L Tris hydrochloride, pH 7.4, 1 mmol/L dithiothreitol, and 0.1 mmol/L phenylmethylsulfonylfluoride. This solution was centrifuged at 40,000 g for 15 minutes, the supernatants from all tubes were discarded, and the pellets were pooled. The pellets were resuspended in 0.25 mol/L sucrose, 50 mmol/L Tris hydrochloride, pH 7.4, 1 mmol/L dithiothreitol, and 0.1 mmol/L phenylmethylsulfonylfluoride. The protein concentration was determined by the Bradford assay[24] with bovine serum albumin used as the standard. Membranes were either used fresh or stored in liquid nitrogen for later use. No loss in receptor activity occurred under these conditions. The use of these human placental membranes was approved by the Human Use Committee for the University of Arkansas for Medical Sciences.

Binding of ^{125}I-labeled proANF 1 to 30, 31 to 67, and 99 to 126. Purified placental membranes were diluted 1:10 in phosphate-buffered saline solution and then incubated with 1 nmol/L ^{125}I-labeled human proANF 1 to 30, 31 to 67, and 99 to 126 (approximately 10,000 counts/min), respectively, in separate polypropylene tubes. Each tube had 100 µl total volume of Hanks' balanced salt solution, pH 7.4, containing 0.1% bovine serum albumin (binding medium). They were incubated at 24° C for 60 minutes. After their respective 1-hour incubations the supernatants were aspirated, the membranes were washed three times with ice-cold phosphate-buffered saline solution containing 0.1% bovine serum albumin, and the membrane-bound radioactivity was measured in a γ-spectrometer. Specific binding was defined as the total binding minus the nonspecific binding in the presence of varying concentrations from 10 pmol/L to 1 µmol/L of the unlabeled atrial natriuretic prohormone peptides. The specific binding for the three ligands at their respective 1 nmol/L concentrations were: proANF 1 to 30, 66%; proANF 31 to 67, 57%; and ANF 99 to 126, 47%.

Analysis of receptor binding data. The receptor binding data were analyzed with the All Fit Dose Response Analysis Program, written in Applesoft Basic by Martin H. Teicher, MD, PhD. This computer program is modified from the original AllFit program of DeLean et al.[25]

Results

Binding of ^{125}I-proANF 1 to 30, ^{125}I-proANF 31 to 67, and ^{125}I-ANF to placental membranes. ^{125}I-proANF 1 to 30, ^{125}I-proANF 31 to 67, and ^{125}I-ANF (99 to 126) were found to bind specifically to placental membranes (Figs. 1 to 3). Unlabeled proANF 1 to 30 displaced ^{125}I-labeled proANF 1 to 30 binding in a concentration-dependent manner on placental membranes (Fig. 1). ANF and proANF 31 to 67 inhibited ^{125}I-labeled proANF 1 to 30 binding at concentrations somewhat above which these peptides are known to circulate, i.e., 10^{-6} mol/L for ANF and 10^{-7} mol/L for proANF 31 to 67 (Fig. 1). Similarly corticotropin, growth hormone, and insulin could displace ^{125}I-proANF 1 to 30 binding

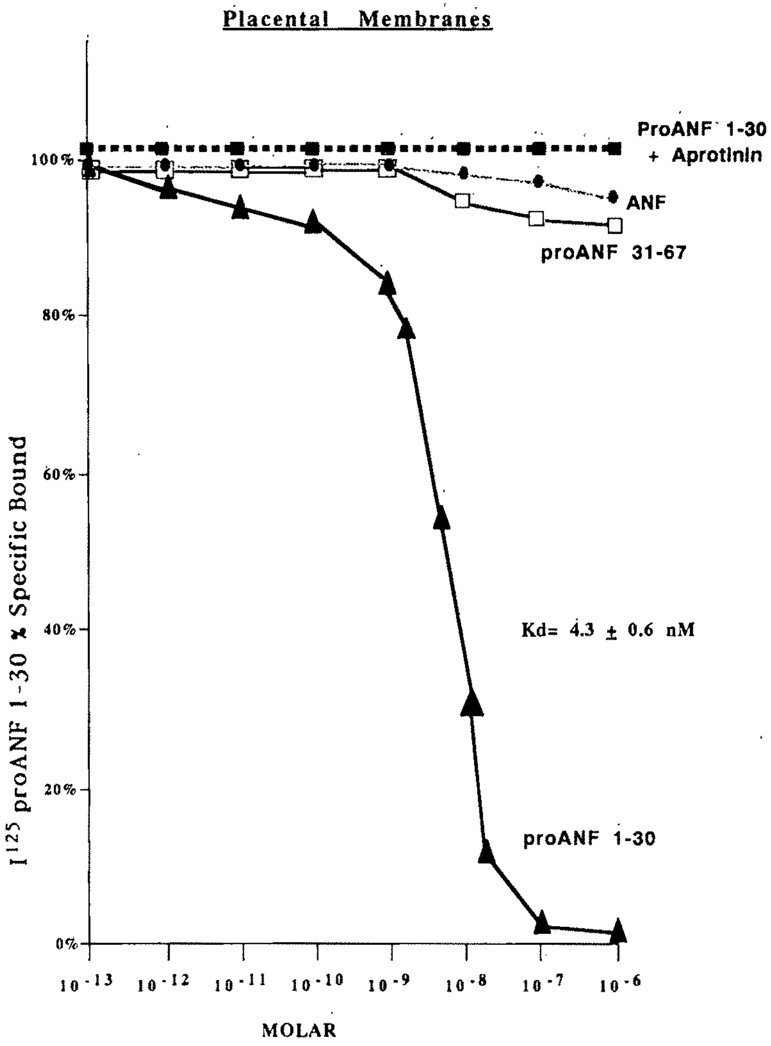

Fig. 1. Concentration-dependent relationship of proANF 1 to 30 binding on placental membranes. ^{125}I-proANF 1 to 30 binding to human placental membranes incubated at 24° C for 60 minutes was inhibited by unlabeled proANF 1 to 30 in a concentration-dependent manner but not by proANF 31 to 67 or ANF. Addition of aprotinin (50 μg/ml) antagonized proANF 1 to 30 specific binding. K_d, dissociation constant.

only at 10^{-4} mol/L concentrations but not at their circulating concentrations (data not shown). Scatchard analysis of the proANF 1 to 30 binding to placental membranes resulted in a straight line, suggesting that these membranes contain a single class of high-affinity binding sites for proANF 1 to 30 with an equilibrium dissociation constant of 4.3 ± 0.6 nmol/L.

The binding of ^{125}I-proANF 31 to 67 to placental membranes was competitively inhibited by unlabeled proANF 31 to 67 between 10^{-9} and 10^{-11} mol/L (Fig. 2). The binding of this peptide hormone could be inhibited by concentrations (10^{-4} to 10^{-7} mol/L) of ANF, proANF 1 to 30, insulin, growth hormone, and corticotropin that are far in excess of their respective circulating concentrations (Fig. 2). Scatchard analysis of the proANF 31 to 67 binding data resulted in a straight line, suggesting that placental membranes contain a single class of high-affinity binding sites for proANF 31 to 67 with an equilibrium dissociation constant of 3.1 ± 0.4 nmol/L.

^{125}I-ANF (99 to 126) also bound to placental membranes (Fig. 3), and its binding was competitively displaced by 10^{-8} to 10^{-10} mol/L of unlabeled ANF but not by proANF 1 to 30, proANF 31 to 67, insulin, growth hormone, or corticotropin in this concentration range (Fig. 3). Scatchard analysis of the ANF binding data revealed a straight line with an equilibrium dissociation constant of 4.9 ± 0.8 nmol/L, indicating a high-affinity binding site for ANF on human placental membranes.

Binding of the three radiolabeled peptides was observed as early as 5 minutes and reached equilibrium at 30 to 40 minutes at 24° C. After 3 hours of incubation at 24° C the amount of specific binding began to de-

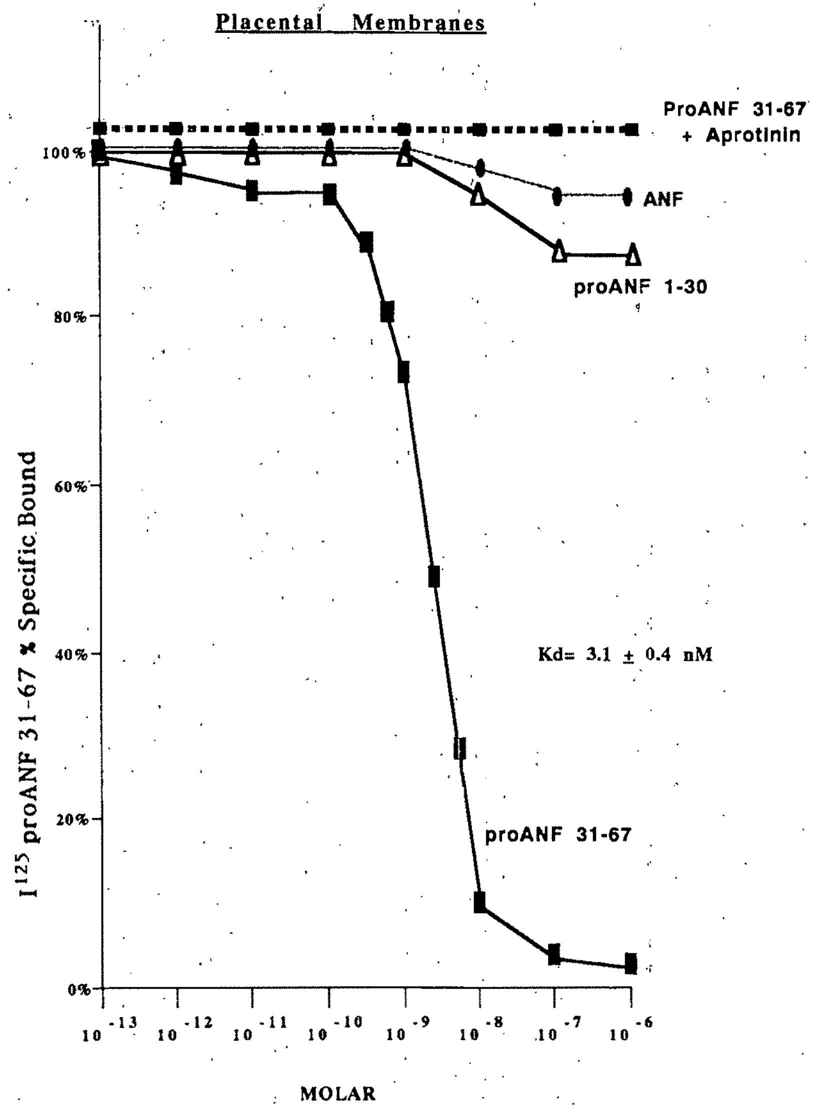

Fig. 2. Competitive binding of ^{125}I-proANF 31 to 67 to placental membranes. ^{125}I-proANF 31 to 67 binding to placental membranes for 60 minutes at 24° C was inhibited by unlabeled proANF 31 to 67 in a concentration-dependent manner but not by proANF 1 to 30 or ANF. Aprotinin (50 µg/ml) antagonized proANF 31 to 67 binding to these placental membranes. K_d, Dissociation constant.

crease. At 4 hours the specific binding of all three peptides had decreased to 50% of that seen at 2 hours. This rapid and reversible binding was also temperature dependent. At 0° C maximal binding was not reached until 60 minutes and did not decrease for up to 4 hours.

Aprotinin (50 µg/ml) blocked the binding of ^{125}I-proANF 1 to 30 (Fig. 1), ^{125}I-proANF 31 to 67 (Fig. 2), and ^{125}I-ANF (Fig. 3), respectively, to placental membranes at 24° C. This reduction of ^{125}I-proANF 1 to 30, ^{125}I-proANF 31 to 67, and ^{125}I-ANF binding was temperature dependent, with a maximal inhibition of the binding of each of these peptides at 4° C with 10 µg/ml of aprotinin, whereas at 24° C 50 µg/ml of aprotinin was necessary for maximal inhibition of binding.

Comment

High-affinity membrane binding sites for ANF (amino acid 99 to 126 of the 126 amino acid ANF prohormone) have been characterized previously in placental membranes.[17-19] The present investigation reveals that proANF 1 to 30 (long-acting sodium stimulator) and proANF 31 to 67 (vessel dilator) each have separate and specific binding sites that are distinct from the ANF binding site. The association of each of their respective binding sites was time and temperature dependent. The binding affinities of proANF 1 to 30, proANF 31 to 67, and ANF on placental membranes were observed near their respective circulating concentrations,[4-16] suggesting that these binding sites may be

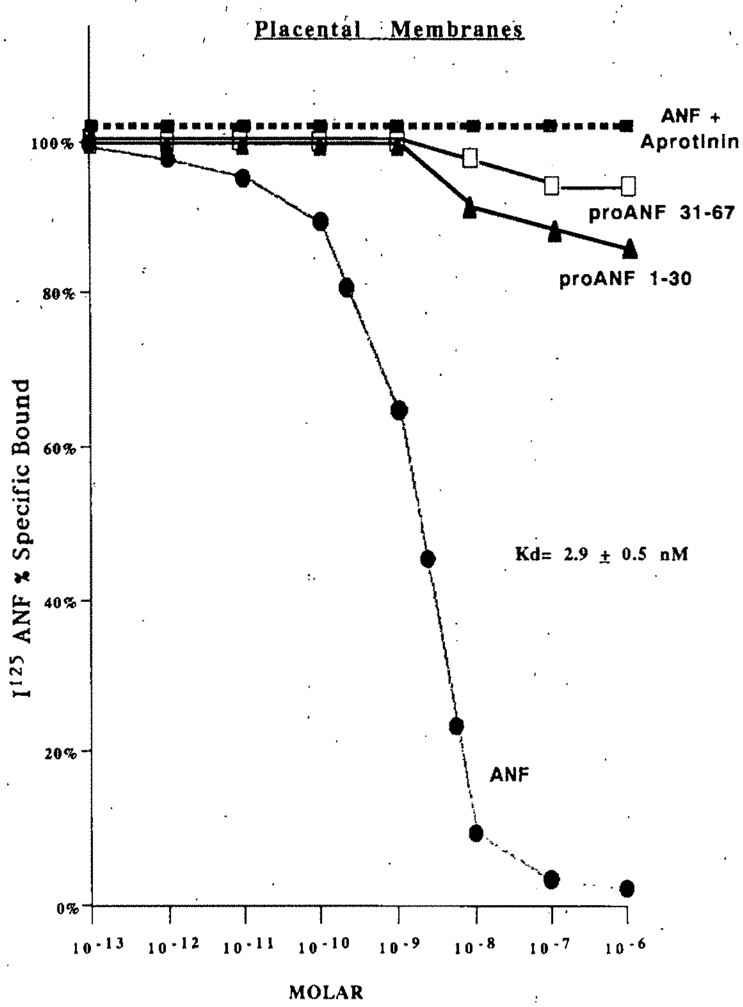

Fig. 3. Competitive binding of ^{125}I-ANF (amino acid 99 to 126 or prohormone) to placental membranes. Placental membranes were incubated at 24° C for 60 minutes with ^{125}I-ANF and increasing concentrations of unlabeled proANF 31 to 67, proANF 1 to 30, or ANF. Aprotinin (50 μg/ml) added to increasing concentrations of ANF antagonized the specific binding of ANF on these placental membranes. K_d, Dissociation constant.

important in mediating fluid and electrolyte homeostasis in human gestation. A study by Hatjis and Grogan[18] indicating that ^{125}I-ANF binds to the placental membrane fraction closer to the fetal circulation than to the maternal circulation is very interesting in this regard since it suggests that certain placental functions may be influenced primarily by the fetal hormonal milieu. ANF levels have been shown to be higher in umbilical arterial plasma than in venous umbilical or maternal plasma, implying fetal synthesis of atrial natriuretic peptides.[26] The possibility that the placenta itself is synthesizing the ANF prohormone awaits further investigation with ANF messenger ribonucleic acid probes of cloned complementary deoxyribonucleic acid. The finding of this investigation that the natriuretic and diuretic peptides proANF 1 to 30, proANF 31 to 67, and ANF have distinct binding sites with nearly equal affinity in placental tissue suggests that proANF 1 to 30, proANF 31 to 67, and ANF may be important in the regulation of fluid and electrolyte transport between fetal and maternal compartments. ProANF 1 to 30 and proANF 31 to 67 are equally potent in comparison with ANF in animal studies in causing a diuresis and excretion of sodium,[3] but the nearly equal binding affinity of each in the placenta cannot be equated with each of the peptides having equal effects on placental homeostasis. The contribution of each of these newly discovered peptides to placental fluid homeostasis and the origin of these peptides in the placenta, whether from maternal, fetal, or placental production, awaits further investigation.

Aprotinin, a protease inhibitor that is widely used in radioimmunoassay systems to prevent proteolysis, clearly antagonized the binding of ^{125}I-proANF 1 to 30, ^{125}I-proANF 31 to 67, and ^{125}I-ANF to placental membranes. Aprotinin previously has been demonstrated to inhibit the binding of human chorionic gonadotropin to its receptor in ovarian plasma membranes.[20] Another protease inhibitor, dansyl-arginyl-(4′-ethyl)piperidine amide, likewise has been shown to inhibit human chorionic gonadotropin binding to its receptor.[27] The exact mechanism of the ability of protease inhibitors to inhibit binding of human chorionic gonadotropin, proANF 1 to 30, proANF 31 to 67, and ANF to plasma membranes is unknown. Since these plasma membranes appear to be rich in proteases,[28] however, it may well be that aprotinin antagonizes the binding of these substances by binding to a protease closely associated with the receptor molecule, as suggested by Wilkes and Hui[20] for the human chorionic gonadotropin receptor, and thereby sterically hinders the entry of these peptides into their binding site on placental membranes. This possible mechanism of action of aprotinin on proANF 1 to 30, proANF 31 to 67, and ANF binding is consistent with the emerging concept that integral membrane proteases are modulators of receptor function.

In conclusion, the presence of specific binding sites for proANF 1 to 30, proANF 31 to 67, and ANF in human placenta is of interest in that it suggests that these three newly discovered peptide hormones may be important in placental hemodynamics, fluid shifts, and electrolyte transport, because the first step in the mechanism of action of most polypeptide hormones is the binding to a receptor in their target tissues. The ability of aprotinin to antagonize the binding of these peptide hormones to placental membranes suggests that integral membrane proteases may be modulators of the receptor function of proANF 1 to 30 (long-acting sodium stimulator), proANF 31 to 67 (vessel dilator), and ANF.

We thank M. Theresa Newton for her excellent technical assistance.

Hexamethylmelamine chemotherapy for persistent or recurrent epithelial ovarian cancer

David H. Moore, MD, Wesley C. Fowler, Jr., MD, Connie P. Jones, BS, and Linda S. Crumpler, RN
Chapel Hill, North Carolina

The purpose of this study was to determine the activity and toxicity of hexamethylmelamine chemotherapy in patients with persistent or recurrent epithelial ovarian cancer. Forty-nine women received hexamethylmelamine 100 to 150 mg/day for 14 days, repeated at 4-week intervals. All patients had previously received at least one chemotherapy regimen, and 46 (94%) had received cisplatin. Among 25 patients with clinically measurable disease there were three complete and two partial responses, for an objective response rate of 20%. The mean progression-free interval for responders was 38.6 months versus 9.6 months for nonresponders or patients with nonmeasurable disease ($p < 0.001$). Thirteen patients are alive, eight with no clinical evidence for disease. Only four patients discontinued therapy because of toxic reactions. Hexamethylmelamine appears to be a well-tolerated drug with activity against ovarian cancer previously treated with cisplatin. (Am J Obstet Gynecol 1991;165:573-6.)

Key words: Ovarian cancer, drug therapy, hexamethylmelamine

In spite of the discovery of cisplatin and its analogs and the development of multiagent chemotherapy regimens for the treatment of epithelial ovarian cancer, fewer than one fourth of women initially seen with stage IIIC to IV disease will ultimately survive cancer. Recurrent ovarian cancer is often drug or radiation resistant and incurable, even with a low tumor burden. There is no standard therapy for persistent or recurrent ovarian cancer that can be considered curative in a majority of cases. Second- and third-line treatments are frequently handicapped by a performance status decreased from advanced disease.

Hexamethylmelamine was introduced into clinical cancer trials in 1964. The mechanism of action of hexamethylmelamine is unknown, although it is structurally similar to the alkylating agent triethylenemelamine and probably does not involve alkylation. Early experiences with single-agent hexamethylmelamine consistently demonstrated activity in epithelial ovarian cancer, with response rates of 15% to 20% in previously treated patients and >30% in patients new to chemotherapy.[1, 2] Hexamethylmelamine is attractive as an anticancer drug because myelosuppression is generally not the dose-limiting toxicity. Nonetheless, a role for hexamethylmelamine in ovarian cancer treatment remains undefined because of the relative lack of large, adequately controlled comparative studies.[3]

We have used hexamethylmelamine for >8 years in the treatment of ovarian adenocarcinoma. The purpose

of this report is to review our experience with this drug in patients with recurrent or persistent ovarian cancer previously treated with cisplatin-based chemotherapy.

Material and methods

Sixty-two patients with recurrent or persistent epithelial ovarian cancer were treated with hexamethylmelamine chemotherapy at the gynecologic oncology service at the University of North Carolina Hospitals between April 1, 1982, and Oct. 31, 1989. Patients were identified by reviewing chemotherapy clinic and disposition conference records. The disposition conference is a weekly multidisciplinary meeting to discuss the evaluation and treatment of all patients with gynecologic malignancies.

Hexamethylmelamine capsules were administered at a dose of 100 to 150 mg/day for 14 days, with courses repeated at 4-week intervals until cancer progression or toxic reaction. Doses were not adjusted according to body surface area calculations. An adequate trial of therapy was defined as the completion of one course of treatment and a follow-up examination. Six patients were excluded from analysis either because they never took the drug ($n = 2$) or they never returned for follow-up ($n = 4$). Additionally, seven women were excluded because hexamethylmelamine was given in combination with other chemotherapy drugs ($n = 2$), recurrent or persistent ovarian cancer was not documented ($n = 1$), or the nature of the primary tumor was uncertain ($n = 4$). Therefore 49 patients formed the cohort for analysis.

Medical records were analyzed to determine survival, the frequency of objective responses (including progression-free interval and response duration), and treatment side effects. Determining objective response rates depended on measurable disease, functionally defined through the ability to measure cancer in two perpendicular diameters by physical examination or radiologic studies. Response criteria included complete response, defined as the disappearance of all measurable disease; partial response, defined as a >50% decrease in the product of perpendicular diameters for measurable disease; stable disease, defined as no change in tumor measurements; and progression, defined as a >50% increase in the product of perpendicular diameters or the appearance of new lesions. A persistently elevated serum CA 125 (>35 U/ml) was considered indicative of disease persistence. Twenty-five women in this series had measurable disease, and 24 had nonmeasurable disease. Patients with nonmeasurable disease were included in survival and toxicity analyses, but were ineligible for response evaluation. All subjects were followed for a minimum of 12 months, except for those who died earlier of cancer. Women with adequate trials of therapy who subsequently were lost to follow-up were presumed dead of disease. Survival statistics were calculated from the initiation of hexamethylmelamine chemotherapy.

Statistical analyses of differences in sample means used a two-sided Student t test. Significance was defined at $p < 0.05$.

Results

The mean age of the 49 patients was 58.8 years (range 26 to 79 years). Eighty-two percent (40/49) of patients had stage III to IV disease when ovarian cancer was first diagnosed, and 93% had grade 2 to 3 tumors. There were no significant differences between patients with measurable versus nonmeasurable disease with respect to age, stage, or tumor grade.

All patients had persistent or recurrent epithelial ovarian cancer and previously had received a minimum of one chemotherapy regimen. Fourteen women had received two, and four women had received 3 prior chemotherapy regimens. Cisplatin-based chemotherapy was previously administered to 94% (46/49) of patients. Sixteen women previously received radiation therapy, including intraperitoneal radioactive chromic phosphate ($n = 12$), pelvic radiation ($n = 2$), or whole abdominal radiation ($n = 1$). One patient received both pelvic radiation therapy and intraperitoneal radioactive chromic phosphate.

Seventy-five percent (18/24) of the women with nonmeasurable disease started hexamethylmelamine chemotherapy because of persistent disease documented at surgical reexploration. Six women started hexamethylmelamine chemotherapy because of inability to complete the initially prescribed therapy, persistent CA 125 elevation after completion of primary therapy, suspicious findings on physical examination or on radiologic study that were not measurable, or refusal to undergo operative reassessment with previous advanced ovarian cancer and large residual tumor volume after surgical debulking. Among the 25 patients with measurable disease, 11 (44%) had tumor masses >5 cm in diameter and 7 (28%) had masses >10 cm in size. The difference in the mean number of hexamethylmelamine courses completed for subjects with measurable (9.0 ± 8.6) versus nonmeasurable (9.6 ± 6.8) disease was not significant.

Seven women with nonmeasurable disease are alive 10 to 35 months (mean 21.3 ± 8.1 months) after the initiation of hexamethylmelamine chemotherapy, and five remain clinically without evidence of disease.

There were three complete and two partial responses among patients with measurable disease, for an objective response rate of 20%. Each objective response occurred in a patient previously treated with cisplatin. All three complete responders remain in clinical remission. One patient with a partial response died at 24 months, and the other is alive with disease at 27 months. Two women currently undergoing treatment at 7 and 28 months are alive with stable disease. The mean progression-free interval for patients with objective responses is 38.6 months (range 14 to 97 months), and the mean progression-free interval for nonresponders plus patients with nonmeasurable disease is 9.6 months (range 1 to 35 months); this difference is significant ($p < 0.001$). No patient whose disease progressed during cisplatin-based chemotherapy responded to hexamethylmelamine.

Nonhematologic toxic reactions to hexamethylmelamine chemotherapy were mild (Gynecologic Oncology Group grade 0 to 1) and generally consisted of either acral paresthesias ($n = 10$) or nausea ($n = 5$). Other complications of treatment included weakness ($n = 3$), myalgias ($n = 2$); and zoster infections ($n = 2$). Myelosuppression was infrequent; three patients had nadir leukocyte counts of $<3000/\mu l$, and no patient's leukocyte count dropped to $<2000/\mu l$. One patient had a nadir platelet count of $94,000/\mu l$. Four patients stopped treatment because of symptoms unrelated to disease progression: nausea, vomiting, and abdominal cramping ($n = 3$); dermatitis ($n = 1$).

Comment

Until it is possible to reliably diagnose ovarian cancer at an early stage, oncologists will continue to face the dilemma of advanced, large-volume disease. Clinical response rates to cisplatin-based multiagent chemotherapy are high, although only 20% to 30% of patients will prove to be in complete pathologic remission at the time of surgical reassessment.[4,5] Disease will recur in as many as 50% of patients in spite of negative findings at second-look laparotomy.[6] Chronic dose-limiting toxic reactions to cisplatin (neurotoxicity, nephrotoxicity, anemia) preclude its use for protracted treatment and indicate the need for alternative therapies.

The activity of hexamethylmelamine in epithelial ovarian cancer was firmly established by Wharton et al.,[2] who reported their series of 54 women treated at the M. D. Anderson Hospital. All patients had stage III to IV ovarian adenocarcinoma, and none had received prior radiation or chemotherapy. Objective responses occurred in 31.5% of patients, with eight complete clinical responses. The test results of the gross specimens of 5 patients were negative for persistent disease at surgical reassessment, and the results of all biopsies were negative in 3 cases. The median disease-free interval was 8 months, and recurrent cancer developed in 70% (12/17) of patients. The results with hexamethylmelamine are similar to results with alkylating agent chemotherapy under similar clinical circumstances.

After surgical staging and tumor debulking, combination chemotherapy is the mainstay of ovarian cancer treatment. Many chemotherapy regimens use cisplatin along with an alkylating agent; therefore second-line therapy of persistent or recurrent ovarian cancer must not be cross-resistant to these agents.

Johnson et al.[7] reported an objective response rate of 28% in a series of 21 women treated with hexamethylmelamine chemotherapy. There were no complete responders. All patients received hexamethylmelamine after manifesting progressive disease while receiving an alkylating agent. Dose modifications were necessary in 90% of patients because of toxic reactions, most commonly nausea and vomiting. Several other investigators have demonstrated the activity of hexamethylmelamine chemotherapy in ovarian cancer resistant to alkylating agents with response rates of 16% to 21%.[8-10] These studies were consistent in the frequency of objective responses, the infrequency of complete responses, and the lack of myelosuppression as a dose-limiting toxicity. Although response rates were modest, some ovarian cancers refractory to alkylating agents evidently are not cross-resistant to hexamethylmelamine.

Response rates achieved with hexamethylmelamine chemotherapy for patients previously treated with cisplatin are more varied. Stehman et al.[11] had no objective responders in their series of 18 patients and concluded that hexamethylmelamine has insignificant activity in cisplatin failures. Rosen et al.[12] contradicted this conclusion when they reported a 25% objective response rate—including four complete responses—among 20 evaluable patients treated with hexamethylmelamine chemotherapy.

Recently, Manetta et al.[13] reported their results for 52 women with advanced ovarian cancer. Cisplatin and cyclophosphamide (with or without doxorubicin) were previously used in 92% of cases. Eight patients (15%) had no evidence of disease after hexamethylmelamine chemotherapy, and five women remained in complete clinical remission through 15 to 65 months of follow-up. Unfortunately, 87.5% of patients categorized as responders had nonmeasurable disease.

The 20% objective response rate to hexamethylmelamine chemotherapy in our series of extensively treated patients is noteworthy. All patients who responded to hexamethylmelamine had previously received cisplatin and had measurable disease. Eight women remain clinically without evidence for disease.

The common dose-limiting toxicities of hexamethylmelamine are gastrointestinal, peripheral neuropathy, and myelosuppression. Most investigators have used hexamethylmelamine doses of 240 to 350 $mg/m^2/day$; dose reductions, treatment delays, or discontinuations were necessary in up to 50% of patients.[1] We chose lower doses of hexamethylmelamine because of our extensively pretreated patient population. The virtual absence of severe (Gynecologic Oncology Group grade 3 or 4) toxic reactions suggests that higher hexamethylmelamine doses may be appropriate.

Since its introduction >25 years ago, a role for hexamethylmelamine in the treatment of epithelial ovarian cancer remains in question. We believe that through the development of well-designed prospective clinical trials an answer can and should be achieved.

Fetal breathing movements before oxytocin induction in prolonged pregnancies

Peter Schreyer, MD, Naomi Bar-Natan, MD, Dan J. Sherman, MD, Shlomo Arieli, MD, and Eliahu Caspi, MD
Zerifin, Israel

Fetal breathing movements were recorded before elective labor induction in 65 patients with uncomplicated prolonged pregnancies. Breathing activity was observed in 41 patients and was absent in 24. Comparison of these two groups indicated that the induction period was significantly shorter and the oxytocin requirement significantly lower in the group with no fetal breathing movements (mean, 319.3 vs 648.5 minutes and 1133.7 vs 2708.4 mIU, respectively). These findings remained valid regardless of Bishop scores. The data suggest that fetal breathing movements are predictive of the effectiveness of oxytocin induction in prolonged pregnancies. (AM J OBSTET GYNECOL 1991;165:577-81.)

Key words: Fetal breathing movements, labor induction, prolonged pregnancy

The optimal management of postterm pregnancy is as yet unestablished, and probably no obstetric disorder is surrounded by more confusion that postdatism.

Physiological placental aging causes progressive uteroplacental insufficiency, which in turn leads to increased rates of fetal asphyxia, oligohydramnios, and in severe cases, nervous system damage and death.[1] The decreased placental blood flow in postdate pregnancies represents a continuum that may in fact begin before 42 weeks' gestation. Studies suggest that perinatal morbidity increases after 40 weeks' gestation.[2, 3]

In uncomplicated, well-established, postterm pregnancies, induction of labor is generally recommended if the cervical score is favorable; however, the proper procedure in cases of unripe cervix remains controversial.[4, 5]

Fetal breathing movements are an integral part of normal physiological development, beginning early in gestation. Significant increase of the incidence of fetal breathing movements by maternal injection of glucose in term pregnancies was previously reported.[6] Studies have shown that fetal breathing activity gradually begins to diminish at 72 hours before labor and ceases completely during the active phase of labor.[7-9] The increase in the level of prostaglandins during labor may exert a dual and simultaneous influence, activating myometrial contractility[10] and inhibiting the fetal respiratory center.[11, 12] Decreased fetal breathing movements have been shown to be a sensitive parameter in distinguishing between true and false premature labor[13-15] and in the diagnosis of true term labor.[16]

The aim of this study was to investigate fetal breathing movements as a possible parameter for the prediction of the effectiveness of oxytocin induction in postdate pregnancies.

Patients and methods

The study group consisted of 65 patients at gestational age 287 to 294 days who underwent fetal testing before the induction of labor at the Assaf Harofe Medical Center between June 1, 1988, and June 1, 1989.

To assure the accurate assignment of gestational age, the study patients were required to meet the following criteria: a reliable last menstrual period (known date); a history of regular menstrual cycles; and one first-trimester or two second-trimester ultrasonographic examinations confirming the menstrual age.

Patients with pregnancy-induced hypertension, diabetes mellitus, previous cesarean section, intrauterine growth retardation, approximate fetal weight >4300 gm, or malpresentation were excluded from the study.

Patients did not take any medication except iron or vitamin supplementation for at least 2 weeks before admission, fasted for at least 8 hours, and did not smoke during the study.

All studies began between 8 and 9 AM when an intravenous infusion of 500 ml 10% glucose was started and administered over a 1-hour period. Nonstress tests were carried out throughout the infusion. Those with reactive NST results were examined for fetal breathing movements within 10 minutes from completion of the glucose infusion, using real-time ultrasonography. Fetal breathing was considered to be present when it was sustained ≥20 seconds, and absent when no sustained movement could be detected within a 45-minute pe-

riod. Results were sealed in an envelope and revealed only at the termination of the entire study.

Patients were then transferred to the delivery unit for cervical scoring with the method of Bishop.[17] Scores ranged from very low (highly unfavorable cervix) (0 to 2), to low (3 to 5), to high (6 to 10). All scores were recorded by the same senior author (N.B-N.). Patients with highly unfavorable cervices were eliminated from the study and treated either expectantly or by intracervical prostaglandin E_2 gel application. Patients were divided retrospectively into two groups according to the presence or absence of fetal breathing movements. Patient data are shown in Table I.

Oxytocin induction was conducted in three stages:

1. Infusion was begun at a rate of 2 mIU/minute and increased by 1 mIU/minute at 30-minute intervals until three contractions per 10 minutes were achieved.
2. This was followed by a latent phase, during which regular uterine contractions began. When the cervix was effaced and dilated 2 to 3 cm, the membranes were artifically ruptured, internal cardiotocography was initiated, and continuous lumbar epidural block was begun.
3. During the final (active) phase, oxytocin was titrated in accordance with intrauterine pressure measurements to 250 to 300 Montevideo Units. Full dilatation of the cervix was considered as the end point of the study. Cardiotocography was continued throughout until delivery. Scalp pH determinations were conducted in cases of suspected monitored fetal distress.

In all patients induction and delivery were performed under the supervision of the same author (N.B-N.).

Results

Of the 65 patients, 41 showed fetal breathing movements and 24 had no fetal breathing movements. More than 90% of the patients in the latter group were delivered of infants spontaneously, compared with 78% of those with breathing activity. Cesarean sections were performed in four patients, all in the group with fetal breathing movements (one with a high Bishop score and 3 with low scores); indications were fetal distress in one case and combined dysfunctional disorders in three cases. Mean fetal weight (3608 and 3728 gm) and incidence of macrosomia (15% and 17%) were similar in both study groups (Table II).

The data concerning time and quantity of oxytocin infused from the onset of induction to the end of the first stage of labor do not include the four patients delivered by cesarean section.

The mean time required to achieve three uterine contractions per 10 minutes was significantly longer in the group with fetal breathing movements (129.6 minutes) than in the patients who showed no fetal breathing movements (72.2 minutes) (Table III). The mean durations of the latent and active phases were 3 hours and approximately 1.5 hours longer, respectively, in the group with fetal breathing movements. The mean oxytocin requirement from onset of induction to the end of the first stage of labor was more than twofold in the group with fetal breathing movements compared with the group without fetal breathing movements (2708.4 and 1133.7 mIU, respectively).

When the patients were differentiated according to Bishop scores, results showed 34 patients with low scores (3 to 5) and 27 with high scores (6 to 10).

Of the patients with low Bishop scores, 24 (>70%) showed fetal breathing movements and 10 did not. Comparison of these subgroups indicated a significantly longer mean induction time (785.2 vs 369.0 minutes) and a significantly higher mean total oxytocin requirement (3348.4 vs 1418.0 mIU) for the patients with fetal breathing movements (Table IV).

Of the 27 patients with high Bishop scores, 13 showed fetal breathing movement and 14 did not. The former subgroup required a significantly longer induction period (396.1 vs 283.9 minutes) and significantly more oxytocin to induce labor (1526.9 vs 930.7 mIU) than the patients without fetal breathing movements (Table V).

Patients with low Bishop scores and no fetal breathing movements reached the end of the first stage of labor after a mean period of 6 hours and 10 minutes of oxytocin infusion, compared with 6 hours and 40 minutes in patients with high Bishop scores and fetal breathing activity. The mean oxytocin requirement was similar in both groups (3.8 and 3.9 mIU/minute).

Comment

Although earlier studies have reported an approximate twofold increase in neonatal mortality associated with postdatism,[18] more recent data suggest that the risk is not clearly increased.[19] The improved outcomes seem to be a result of closer fetal surveillance in postterm pregnancies. In a review of antepartum testing in

postterm pregnancies, it was reported that ultrasonographic examination with a 3 cm vertical amniotic fluid pocket resulted in the lowest number of perinatal deaths (1.8/1000), followed by use of contraction stress testing (2.5/1000). Ultrasonography with a 1 cm pocket and biweekly nonstress testing were less effective (5/1000 and 6/1000, respectively).[20] In spite of these measures, however, an increased incidence of meconium-stained amniotic fluid, meconium aspiration syndrome, fetal distress, and low Apgar score was noted.[19, 21, 22] Although induction of labor in postterm pregnancies has generally been indicated,[23] according to recent studies such active management may not be beneficial.[24, 25] The major objections are the increased incidence of prolonged labor and cesarean section when induction is attempted under conditions of an

*The two-tailed Student *t* test for independent samples.

unfavorable cervix.[24] One prospective study has revealed, in contrast to previous reports,[4, 17] that cervical examination before induction seems to be a poor screening test to determine the outcome of labor.[26] No other prognostic parameters for labor induction have been described.

Fetal breathing movements have been shown to diminish gradually beginning 72 hours before labor. This may reflect a dual response to increased prostaglandin synthesis, which influences both the fetal respiratory centers and myometrial contractility.

In this study, of the 65 patients with postdate pregnancies who underwent ultrasonographic examination before labor induction, 41 (43%) showed sustained fetal breathing movements, which suggested a low probability of incipient spontaneous labor. It is of interest that 68% of the group with fetal breathing movements had low Bishop scores, in contrast with 42% of the group without fetal breathing movements ($p < 0.03$), indicating a probable connection between fetal breathing activity and ripeness of the uterine cervix. The induction period and the oxytocin requirement were significantly lower in the group without fetal breathing movements than in the group with fetal breathing movements, regardless of the Bishop scores.

The optimal conditions for labor induction were a favorable cervix and absence of fetal breathing activity. Patients with high Bishop scores, whether in the group with or without fetal breathing movements, were relatively easily induced (mean time, 6 hours and 40 minutes, and 4 hours and 44 minutes, respectively). In the absence of a favorable cervical score, fetal breathing movements proved to be an important predictive parameter of inducibility. Thus in patients with low Bishop scores and sustained fetal breathing activity, the mean induction period was 13 hours, more than double that in patients with low Bishop scores and an absence of breathing activity (mean, 6 hours and 10 minutes). The amount of oxytocin administered per time required was higher in the group with fetal breathing movements than in the group without fetal breathing movements (4.3 and 3.8 mU/minutes; the total oxytocin requirement was 60% lower in the group without fetal breathing movements.

In conclusion, fetal breathing activity recorded before induction of labor in postdate pregnancies seems to be a reliable indicator of the time and quantity of oxytocin required throughout labor. Further prospective studies are necessary to confirm these results.

Risks associated with an elevated maternal serum α-fetoprotein level

Barbara F. Crandall, MD, Linda Robinson, MS, and Peggy Grau, MD
Los Angeles, California

Among 58,187 women tested, 1002 had a maternal serum α-fetoprotein measuring ≥2.5 multiples of the median after correction for race, weight, and insulin-dependent diabetes. They were stratified into three groups: group 1, 2.5 to 2.9; group 2, 3.0 to 5.0; group 3, ≥5.0 multiples of the median. The initial risk of a serious abnormality detected at ultrasonography or amniocentesis was 17% (5%, 12%, and 65% in groups 1, 2, and 3, respectively). After correction for twins and dates, this risk became 23% (7%, 18%, and 71% in groups 1, 2, and 3, respectively). Among the women with high maternal serum α-fetoprotein levels, 556 (77%) had normal ultrasonographic and amniocentesis studies, and the risk of adverse pregnancy outcome was 27% (19%, 29%, and 70% in groups 1, 2, and 3, respectively). There was a statistically significant increase in late fetal and perinatal death, prematurity and growth retardation, oligohydramnios, abruptio placentae, preeclampsia, and congenital abnormalities. The overall risk for abnormality or adverse outcome was 24% in group 1, 41% in group 2, and 91% in group 3. (AM J OBSTET GYNECOL 1991;165:581-6.)

Key words: Neural tube defects, maternal serum α-fetoprotein

Maternal serum α-fetoprotein (AFP) screening was initially designed to identify neural tube defects.[1] This test may also detect other serious abnormalities, including fetal death.[2] In addition, women with high maternal serum AFPs and normal ultrasonographic and amniocentesis studies have shown an increased incidence of adverse pregnancy outcome.[3-5] The purpose of this report is to compare the incidence of open neural tube defects, other fetal abnormalities, or death detected at ultrasonography and amniocentesis and also the risk of poor pregnancy outcome in women with slight, moderate, and greatly elevated maternal serum AFPs.

Material and methods

Patients were identified from two sources. Of these patients 8787 with known pregnancy outcome and 1400 who were tested later were part of a pilot maternal serum AFP screening study carried out between 1980

and 1982 (2.0% had a single maternal serum AFP value measuring ≥2.5 multiples of the median). Another 48,000 patients were tested between 1986 and 1989 as part of the California Maternal Serum Screening program. After correction for maternal weight, race, and insulin-dependent diabetes, 1002 (1.7%) had a maternal serum AFP value measuring ≥2.5 multiples of the median. Two hundred eighty-one (28%) were excluded because of too advanced or incorrect dates, a twin pregnancy with maternal serum AFP levels <4.5 multiples of the median, refusal to participate in further testing, and a normal repeat maternal serum AFP level; these women had gestations of <18 weeks when seen, and their first maternal serum AFP value measured between 2.5 and 2.9 multiples of the median. Except for this last group, this study is based on a single high maternal serum AFP. This report is based on the 721 (1.2%) that remained elevated after these exclusions. The women studied were a low-risk group for whom amniocentesis was not indicated because of maternal age, previous neural tube defect, or other reason. The control population was a group of 1100 women who had had a normal maternal serum AFP level and whose pregnancy outcome was known. Both study and control groups included approximately equal numbers of women receiving obstetric care through private obstetricians or health maintenance organizations and comprised few clinic patients. In general, these women sought early obstetric care and were therefore probably at lower risk for low birth weight or prematurity.

Maternal serum AFP determinations were done by radioimmunoassay before 1985 and after 1985 by enzyme immunoassay with the Abbott kit. Assays were done in duplicate and intraassay and interassay variations were <5% and 10%, respectively. All women received genetic counseling, and a complete pregnancy and family history was taken. Each patient underwent a detailed ultrasonographic examination initially and usually additional ultrasonographic examinations later if no explanation for the high maternal serum AFP level was found. Gestational dates were corrected if there was a discrepancy of ≥10 days with menstrual date. Amniotic fluid AFP was measured in the same way as AFP in maternal serum, and all samples were tested with acetylcholinesterase gel electrophoresis and chromosome analysis.

Results

One hundred two women who had two elevated maternal serum AFP levels and 900 who had a single elevated maternal serum AFP value were stratified into three groups by degree of elevation (Table I). Initially, 393 (39.2%) had levels between 2.5 and 2.9 multiples of the median (group 1), 473 (47.2%) between 3.0 and

4.9 multiples of the median (group 2), and 136 (13.6%) ≥5.0 multiples of the median (group 3). After 28% were excluded, as already described, 267 (37%), 328 (45.5%), and 126 (17.5%) remained in groups 1, 2, and 3, respectively. Four categories of abnormalities were detected by ultrasonography and amniocentesis: neural tube defects, other serious abnormalities, fetal death, and oligohydramnios. This last category included only cases without another explanation for the oligohydramnios. Abnormalities were listed in one category only; for example, death plus a neural tube defect was included only under neural tube defects. Twins were considered as a single fetus so that abnormalities in one or both were counted only once.

The information of most interest to the primary physician or clinic is the risk of a serious abnormality or neural tube defect at the time of referral and before exclusions at the Prenatal Diagnosis Center. The risk for any abnormality, including death, was 16.5 (4.6%, 12.3%, and 65.4% in groups 1, 2, and 3, respectively). Group 2 contained the most cases of spina bifida and group 3 the most cases of anencephaly. There were four twin pregnancies with a neural tube defect—three in which one fetus had anencephaly and one in which one had spina bifida.

Other serious abnormalities are identified in the footnote to Table I. The overall risk for this group was 3.4% (1.3%, 2.5%, and 12.5% in groups 1, 2, and 3, respectively). All cases of renal agenesis, multicystic kidneys, and urinary tract obstruction had marked oligohydramnios. The overall risk for fetal death detected at the initial ultrasonographic examination was 6.6% (1.0% in group 1, 6.1% in group 2, and 24.3% in group 3). In four cases this affected one twin and in two cases both twins. The overall risk for unexplained oligohydramnios detected at initial ultrasonography was 1.0% (0.5%, 0.4%, and 4.4% in groups 1, 2, and 3, respectively). Six of these aborted spontaneously, and the pregnancy was electively terminated in four others.

Of the 721 women with a high maternal serum AFP level, 556 (77%) had normal ultrasonographic or amniocentesis studies and underwent follow-up to determine the incidence of adverse pregnancy outcome. One of the complications listed in Table II was noted in 26.8%. Fetal or perinatal death was defined as death occurring after 26 weeks and within 28 days of birth; oligohydramnios was moderate or severe and not evident at the initial ultrasonographic examination; prematurity or low birth weight was delivery before 37 weeks or weight <2500 gm or both; abruptio placentae was separation of >15% of the placenta; preeclampsia was a blood pressure of 140/90 mm Hg or an increase in the systolic or diastolic pressure of 20 or 10 mm Hg, respectively, on two readings 6 hours apart, plus proteinuria, edema, or both; a significant congenital abnormality was one not identified at the initial ultrasonographic examination but did not include minor defects such as hydrocele or pilonidal dimple.

Results of the follow-up studies are shown in Table III. There was a statistically significant increase in the incidence of fetal and perinatal death, oligohydramnios, and prematurity or low birth weight in groups 1, 2, and 3. The increased risk was only significant in group 3 for both abruptio placentae and preeclampsia and in group 2 for congenital abnormalities. In the last category the lack of statistical significance is probably explained by the small number of cases in group 3. Death occurred in one twin in one case and in both twins in three cases. Prematurity or low birth weight occurred in one twin in one case (which also had a complete placenta previa) and in both twins in two cases. Fetal death occurred in 8 (73%) of the 11 cases

of severe to moderate oligohydramnios detected after a normal initial ultrasonographic examination and premature delivery occurred in the remainder. Two infants are alive and well, and one continues to have severe respiratory problems.

Details of the congenital abnormalities detected after birth are shown in Table IV. It is important to emphasize that each pregnancy outcome is listed only once and usually under the primary condition. For example, when prematurity and an abnormality occurred, the outcome was listed only once, as a congenital abnormality.

The risk of an adverse pregnancy outcome after a normal ultrasonographic examination and amniocentesis was 18.5%, 28.5%, and 70.2% in groups 1, 2, and 3, respectively. This risk was 88% for a small group of women with maternal serum AFP levels measuring ≥10.0 multiples of the median. The overall risk of an adverse outcome after a high maternal serum AFP value increased from 24% in group 1 to 41.2% in group 2 and 91.3% in group 3 (Table V).

Comment

In this series of 58,187 women, 99.7% of whom had a single maternal serum AFP test, 1.7% had a maternal serum AFP level ≥2.5 multiples of the median after correction for maternal weight, race, and insulin-dependent diabetes, and levels remained elevated after exclusions in 721 (1.2%), mostly because of incorrect dates and twins. The first goal of the study was to compare the risks of an abnormality detected by ultrasonography or amniocentesis in women with mild, moderate, and high elevations of maternal serum AFP. The risk of an open neural tube defect increased from 1.8% in women with maternal serum AFP levels between 2.5 and 2.9 to 24.3% at levels ≥5.0 multiples of the median. Other studies report similar experiences although cutoff levels and comparative degrees of elevation vary. Nelson et al.[3] compared the incidence of neural tube defects in women with maternal serum AFP values between 2.5 and 4.5 multiples of the median and ≥5.0 multiples of the median after two elevated maternal serum AFPs. Of these, 2.4% occurred in the first group and 21% in the second group. Three other reports cite incidences of 6.4% at levels ≥2.0 multiples of the median and 19% and 15% at levels ≥2.5 multiples of the median, usually after two maternal serum AFP tests.[6-8]

In our study 6.7% of women with maternal serum AFP values measuring 2.5 to 2.9 and 70.6% with values ≥5.0 multiples of the median were found to have a serious fetal abnormality at ultrasonography or amniocentesis. Nelson et al.[3] reported an incidence of 4.0% for maternal serum AFP levels between 2.5 and 4.5 and 50% at values ≥5.0 multiples of the median. Their results included one case of placental hemangioma and two abdominal pregnancies. The last complication has been noted previously; Cederquist et al.[9] reported elevated maternal serum AFP values in two of five cases of tubal pregnancy. In our series 21% of the serious abnormalities, excluding fetal death and oligohydramnios, affected the urinary tract; these were identified by ultrasonography. Another 21% were associated with chromosome abnormalities, including two cases of trisomy 18, one case of trisomy 13, two partial monosomies, two partial trisomies, and one with an unidentified marker chromosome. These findings underline the importance of fetal chromosomal analysis after an elevated maternal serum AFP value.

The second part of our study was to determine the risk of an adverse pregnancy outcome in spite of a normal ultrasonographic examination and amniocentesis. It is important to note that there was no evidence of oligohydramnios or other problem at the initial ultrasonographic study. Each case was identified only once, usually in the primary category; for example, if a malformation was complicated by prematurity or death, it was included in the malformation category only. Nelson et al.[3] reported pregnancy complications in 16% of women with maternal serum AFP values measuring 2.5 to 4.5 multiples of the median and 33% at values ≥5.0 multiples of the median after normal amniocentesis results. Other series report increased risks, varying between 25% and 47%.[3, 6-8, 10] We found

Table V. Risk of adverse outcome after high maternal serum AFP value*

≥5.0	70.6	70.3	91.3
TOTAL	22.9	26.8	43.6

*After exclusions.

a statistically significant increased risk for each type of abnormal outcome compared with the control group of women with normal maternal serum AFPs. Burton[11] reported an overall adverse outcome risk of 26% after an unexplained high maternal serum AFP value, 6% for fetal or neonatal death, 15% for low birth weight, and 6.2% for congenital abnormalities. The increased incidence of congenital malformations may help to explain the relationship of poor pregnancy outcome and unexplained high maternal serum AFP results. With the possible exception of the one case of clubfoot in our series (Table IV), the other malformations most likely resulted from a primary developmental defect arising in the first 2 months of gestation. Their association may be coincidental or the result of a common cause affecting either AFP production or its excretion in the fetus or some pathologic process in the placenta that began in the first trimester and permitted greater transfer into maternal serum. The first two are unlikely in view of the normal amniotic fluid AFP level. The third is supported by a report of a higher incidence of chronic villitis and uterine vascular disease in the placentas of women who had a high maternal serum AFP value compared with those who had normal test results.[12] Additional studies of placental abnormality may help to identify women at greater risk for poor pregnancy outcome.

Although there is general agreement concerning the increased risk of adverse pregnancy outcome after an unexplained high maternal serum AFP value, there is no consensus regarding the need or the method for monitoring these pregnancies. Additonal maternal serum AFP tests are unlikely to distinguish between high-risk and low-risk populations. Hamilton et al.[5] compared pregnancy outcomes in women who had one and two high maternal serum AFP values and found no significant difference in the incidence of problems, although these appeared to be more severe after two elevations. Our adverse outcome risks after a single measurement of maternal serum AFP are consistent with others who used two measurements.[3, 6, 7] In most of these a second test was done within 2 weeks of the first one. Maternal serum AFP values in the third trimester generally have not been helpful in predicting complicated pregnancy outcomes.[13, 14] For the present, repeated ultrasonographic examinations are recommended to detect developing growth retardation, and detailed pathologic studies are recommended on all placentas.

We thank Dr. Donald Guthrie for statistical analysis.

Study of 156 cases of polyhydramnios and congenital malformations in a series of 118,265 consecutive births

Claude G. Stoll, MD, Yves Alembik, MD, and Beatrice Dott, MD

Strasbourg, France

Polyhydramnios associated with congenital anomalies was studied over nine years in 118,265 consecutive pregnancies. The prevalence of this association was 1.32% (156 cases). A case-control study allowed the examination of genetic and environmental factors for the origin of polyhydramnios associated with congenital malformations. Diagnosis of polyhydramnios associated with congenital malformations was performed prenatally in 41% of the cases; 16% of the infants were stillborn. Fifty-five percent of the cases had more than one malformation, 13.4% of them had a chromosomal aberration, and 32% had multiple malformations that do not constitute a syndrome. There was an increase of consanguinity in the parents of our patients. The incidence of polyhydramnios and congenital anomalies in first-degree relatives was 3.8%, and first-degree relatives had more malformations than the controls had (8.3% vs 3.2%). Our study demonstrated the low capacity of a general prenatal screening program because the diagnosis of malformations associated with polyhydramnios was made in only 41% of the cases and only six of 21 chromosomal abnormalities were diagnosed prenatally. We recommend the use of fetal chromosome analysis and careful ultrasonographic examination in every pregnancy complicated by polyhydramnios. (AM J OBSTET GYNECOL 1991;165:586-90.)

Key words: Polyhydramnios, congenital anomalies, congenital malformations, prenatal diagnosis, chromosonal abnormalities

The incidence of polyhydramnios varies between 0.4% and 1.5%.[2] The diagnosis of polyhydramnios, which was usually made clinically, was associated with an increased frequency of complications in both mother and fetus. In 358 clinically diagnosed cases of polyhydramnios Queenan and Gadow[1] found that 24.6% had diabetes mellitus, 11.5% had erythroblastosis fetalis, 8.4% had multiple births, 1.5% had acute polyhydramnios, and 20% had congenital anomalies; 34% of the cases of polyhydramnios were idiopathic. Since that landmark report, the definition of polyhydramnios has shifted from a clinical to an ultrasonographic one. Here we consider only polyhydramnios associated with congenital malformations. Data on 156 cases of polyhydramnios occurring among 118,265 consecutive pregnancies delivered in Alsace in northeastern France from 1979 to 1987 are reported. A case-control study allowed the examination of genetic and environmental factors for the origin of polyhydramnios associated with congenital malformations. Complete ascertainment of pregnancies with polyhydramnios and congenital malformations in a defined geographic area provides an opportunity to study the epidemiologic association.

Material and methods

The malformations in this study came from 118,265 consecutive births of known outcome, including 814

Table I. Prevalence of polyhydramnios with one fetal malformation and with more than one fetal malformation

	No.	%	*Prevalence per 10,000 births*	*Sex ratio (male/female)*
Polyhydramnios plus one malformation	70	44.9	5.91	1.18
Polyhydramnios with several malformations	86	55.0	7.27	1.15
Chromosomal abnormalities	21	13.4	1.77	1.33
Nonchromosomal recognized syndromes	15	9.6	1.26	1.14
Multiple malformations without recognized syndromes and without chromosomal abnormalities	50	32.0	2.70	1.08

stillborn babies, registered in our registry of congenital malformations, which covers the "Department du Bas-Rhin" in which Strasbourg is located. Our registry is described elsewhere.[3] Briefly, the newborns of 11 hospitals were examined for the period from Jan. 1, 1979, to Dec. 31, 1987. No deliveries took place at home in the area under study. All newborn children were registered within the first nine days post partum, as were all fetuses with a minimum age of 20 weeks. New cases diagnosed up to 1 year after birth also were registered.

When a suspected or confirmed case was located, the requested information was checked by the doctor in available records: prenatal consultation records, maternity files, neonatal unit files, autopsy reports, outpatient clinic files, and pediatric and surgery files.

Diagnosis of polyhydramnios was made ultrasonographically. All scans were obtained with a real-time sector scanner with the use of a 3.5 to 5.0 or 7.5 MHz transducer of appropriate focal length. The scans were obtained in a routine fashion between 16 and 27 weeks of gestation. Polyhydramnios was diagnosed when more than one pocket of amniotic fluid >7 cm^4 was noted in a vertical dimension. More than 90% of the pregnant women of our region have antenatal ultrasonography.

For each case more than 50 factors included in the registration forms were studied: parity and previous pregnancies, parental age, residence, education, ethnic origin, length, head circumference and weight at birth, inheritance, cytogenetics, occurrence in twins, environmental factors, seasonality, and pregnancy.

For each case a control was studied. The control was a normal child of the same sex born after the case in the same maternity hospital. For seasonality studies the monthly occurrence of all normal births from 1979 to 1987 was chosen as a control rate. For sex ratio, controls were the normal newborn population.

Statistical analysis was obtained by the Statistical Analysis System[5] procedure software package. Statistical comparison was by χ^2 test with Yates' correction for the characteristic under study in cases and in controls and by Student's t test for comparison of means. When it could not be assumed that variances were equal, an adapted t test was used. Odds ratio values were analyzed by χ^2 test.

Results

During the study period 156 cases of polyhydramnios were detected in a total of 118,265 consecutive births, representing an overall prevalence of 1.319 for polyhydramnios associated with congenital malformations detectable at birth and until 1 year of age (Table I). The numbers of cases by year were 15, 14, 21, 25, 26, 14, 11, 12, and 18 from 1979 to 1987, respectively.

One hundred twenty-one children (77.5%) were live births, 25 (16.0%) were stillbirths, and 10 (6.4%) were terminated pregnancies. Diagnosis of malformation was performed at birth in 68 cases (43.6%), during the first week of life in 16 newborns (10.2%), and during the first year of age in eight children (5.1%). Diagnosis of an anomaly was performed prenatally in 64 of 156 cases (41.0%).

There were 70 (44.9%) cases with only one malformation and 86 (55.0%) cases with more than one malformation. The malformations associated with polyhydramnios are listed in Table II. The expected number of each specific malformation was calculated from the frequency of that specific malformation in infants with multiple malformations without polyhydramnios who had been registered during the period from 1979 to 1987; chromosomal abnormalities were excluded. These other malformations allowed us to separate these cases into recognized syndromes (chromosomal and nonchromosomal) and nonrecognized syndromes (multiple malformations) (Table I).

The sex ratios are shown in Table I. Overall sex ratio was 1.16 (84 males, 72 females).

There were no differences between parents of fetuses with polyhydramnios with malformations and control parents with respect to the distribution of parity and previous pregnancies, previous unproductive pregnancies, previous stillbirths, parental age (mean maternal and paternal ages, 27.7 and 30.5, respectively), ethnic origin, residence, and education.

Numbers do not sum because some patients had malformations in more than one additional system.

*$p = 0.05$.

†$p = 0.001$.

At birth, the mean weight, length, and head circumference of malformed children with polyhydramnios were, respectively, 3003 gm (controls, 3297; $p < 0.05$), 47.1 cm (controls, 49.4; $p < 0.001$), and 34.4 cm (controls, 34.6; not significant) and the weight of the placenta was 520 gm (controls, 596; $p < 0.05$). Analysis after standardization for sex and gestational age (<36, 36 to 38, and >38 weeks) gave the same conclusions.

Factors associated with malformed fetuses with polyhydramnios

Genetic factors

CONSANGUINITY OF PARENTS. Consanguinity of parents was admitted in 5.1% of the cases (controls, 1.1%; $p < 0.001$). Inherited mendelian conditions were excluded.

An inherited mendelian condition was present in nine cases. Six infants had nonchromosomal syndromes.

CYTOGENETICS. Karotypes were obtained in 80 cases (57.5%). Of these, 59 were normal; the others were as follows: six Down syndrome, 13 trisomy 18 syndrome, and two autosomal deletions (one 18q− and one 4p−). Five of the infants with Down syndrome had no visceral malformation, and one had duodenal atresia and ventricular septal defect. Eleven of the 13 children with trisomy 18 had cardiac defect (ventricular or atrial septal defect, patent ductus arteriosus, bicuspid aortic or pulmonary valves), intestinal malrotation, megaureter, and cleft palate. The two infants with autosomal deletions had facial dysmorphia only. Of the 25 cases in which karyotype was obtained prenatally, only six abnormalities were present (one Down syndrome and five trisomy 18 syndrome).

Among our 156 index patients, four twins (2.5%) were observed (controls, 2.6%). Each twin had an unaffected twin sibling.

One mother and five siblings had the same nonmendelian inherited anomaly as the proband (3.8%), 11 second-degree relatives had the same anomaly as the proband, and 13 first-degree relatives had other malformations (8.3%) (controls, 3.2%, $p < 0.05$).

Environmental factors. Odds ratios for risk factors were evaluated. No significant difference was found between congenital malformations associated with polyhydramnios and controls with regard to the risk factors studied: diabetes, epilepsy, x-ray films, arterial hypertension, fever, "flu," medication, cigarettes, occupational exposure, and parental age (Table III).

Table III. Odds ratio and 95% confidence interval for risk factors compared with controls

Risk factors	*Odds ratio*	*95% Confidence interval*
Diabetes	1.80	0.45-7.15
Epilepsy	1.01	0.99-1.03
X-ray films	0.02	0.006-0.099
Arterial hypertension	0.52	0.21-1.24
Fever	0.029	0.002-0.397
Contraception	0.48	0.18-1.24
"Flu"	0.77	0.28-2.08
Cigarettes	1.15	0.69-1.93
Drugs	0.03	0.005-0.316
Occupational exposure		
Mother	1.61	0.85-3.03
Father	1.35	0.72-2.53
Maternal age	0.63	0.38-1.07
Paternal age	0.67	0.39-1.15

Comment

Polyhydramnios is common, occurring in 0.4% to 1.5% of pregnancies.[1, 2] Congenital anomalies are more common than polyhydramnios.[3] Both are found together in as many as 20% of the cases of polyhydramnios.[4] They should therefore lend themselves to epidemiologic studies. However, there are no unequivocal epidemiologic data on congenital malformations associated with polyhydramnios, because both are difficult to ascertain accurately.

Data on congenital malformations associated with polydramnios have been collected in different ways.[1, 4, 6, 7] In our series >90% of pregnant women had ultrasonographic examination; therefore the overall incidence of congenital malformations associated with polyhydramnios (1.32%) is certainly not too far from the true incidence of this association. The comparison of our data seen in the tables with those of other series shows a lower incidence in the study of Hill et al.[6] (0.98%).

Few series have evaluated an unselected obstetric population for ultrasonographically detectable polyhydramnios.[8, 9] Ten of the 12 cases of Quinlan et al.[9] had a congenital anomaly that led to death in all but two of these infants. Hill et al.[6] detected 102 cases of polyhydramnios among 10,214 patients studied; 10 of these 102 infants were malformed. In the review of pregnancies complicated by hydramnios undertaken by Landy et al.[7] 99 cases were ascertained. Thirteen of them (three being twins or triplets) had associated malformations.

In our series the most common congenital defects associated with polyhydramnios were congenital heart disease, musculo-skeletal malformations, and anomalies of the gastrointestinal tract. This is in agreement with what is known of the physiopathologic features of polyhydramnios.[8, 10, 11] We also noted more diaphragmatic hernias and facial malformations than expected and fewer cases of spina bifida, unilateral renal agenesis, renal cysts, and abdominal wall defects than expected.

Prevalence of chromosomal abnormalities was 1.77% (9.6% of our cases). As this prevalence is not given in the other series it is difficult to know if this prevalence is high or low. In the French nationwide program for prenatal diagnosis of chromosomal abnormalities a new indication was added in 1986, the study of the fetal karyotype after the presence of "signes d'appel" ("calling signs" such as the discovery of a fetal malformation, a small-for-dates fetus, polyhydramnios, or oligohydramnios).[12] Of 2563 fetal karyotypes studied so far, 299 were abnormal (3.7%), which is only about a third of what we have found in our series that took only polyhydramnios into account.

Consanguinity of the parents of fetuses with congenital malformations associated with polyhydramnios is not mentioned in the other studies. In our study 5.1% of the parents were consanguineous. Six first-degree relatives of patients with congenital malformations associated with polyhydramnios had the same nonmendelian inherited malformations. This last frequency is more than twice that of the controls. These conclusions have to be taken into account for genetic counseling.

Maternal epilepsy, hypertension, and fever during pregnancy were no more common among the mothers of the fetuses with congenital malformations associated with polyhydramnios than among controls. During the pregnancy in question 13.1% of the women had threatened abortions, which is significantly different from the controls ($p < 0.01$). Diabetes mellitus was more frequent in the mothers of the children with congenital malformations associated with polyhydramnios than in the controls (4.5% vs 2.1%), but the difference was not statistically significant. In the study of the literature (see Hill et al.[6]) polyhydramnios was associated with maternal diabetes mellitus in 14.7% to 26.3% of cases, in fetuses with or without congenital malformations. In our series polyhydramnios was taken into consideration only when it was associated with fetal malformations. Our study demonstrates that there is no statistically significant increase in diabetes mellitus among the mothers of infants having polyhydramnios associated with congenital malformations.

In our series the diagnosis of congenital malformations was performed prenatally in 41.0% of the cases. In the series of Landy et al.,[7] 99 cases of pregnancy complicated by hydramnios were studied. Prenatal diagnosis of congenital malformations was performed in only seven cases out of 21 with congenital malformations associated with polyhydramnios.

In our patients with chromosomal abnormalities a congenital malformation was detected prenatally at ultrasonographic examination in only one fetus with trisomy 21 syndrome (duodenal atresia) out of six cases and in five with trisomy 18 syndrome out of 13 cases (28.5% of all cases). In the 15 other cases of chromosomal abnormality no anomaly except polyhydramnios was detected at routine ultrasonographic examination. Benacerraf et al.[13] were able to detect 80% of fetuses with trisomy 18 at ultrasonographic examination. In our series seven cases of trisomy 18 could have been detected if level II and III ultrasonographic examinations had been performed, but seven fetuses with chromosomal anomalies (4.5%) (three Down syndrome, two trisomy 18, and two autosomal deletions) would not have had ultrasonographic detection because they had no malformations except mild facial dysmorphia and mental retardation. Therefore we recommend the use of level II or III ultrasonographic examination in every pregnancy complicated by polyhydramnios.[13] When no malformation at level III ultrasonographic examination is detected, fetal chromosome analysis has to be discussed.

Regulation of atrial natriuretic peptide release in pregnancy: Responses to posture

Sandra A. Lowe, MB,[a, b] **Graham J. Macdonald, MD,**[b] **and Mark A. Brown, MD**[a]
Sydney, Australia

The response of plasma atrial natriuretic peptide to three changes in posture that alter atrial stretch was examined in the late phase of pregnancy: (1) after 20 minutes in lateral recumbency, remaining upright for 2 hours decreased median plasma atrial natriuretic peptide values from 37.8 (25th percentile, 22.9 and 75th percentile; 64.2) to 21.8 (10.1 and 28.4) pg/ml in pregnant women ($p < 0.05$) and from 39.2 (27.8 and 51.2) to 24.0 (18.9 and 35.4) pg/ml ($p < 0.001$) in age-matched nonpregnant women; (2) prolongation of lateral recumbency from 20 to 80 minutes increased median plasma atrial natriuretic peptide levels from 31.9 (25.6 and 37.3) to 47.8 (33.0 and 74.6) pg/ml in pregnant women ($p < 0.001$) and from 36.5 (22 and 58.6) to 54.0 (36.3 and 111.7) pg/ml in nonpregnant women ($p < 0.01$); (3) adoption of supine posture during the late phase of normal pregnancy did not alter median plasma atrial natriuretic peptide values significantly [30.4 (26.7 and 42.5) pg/ml during lateral recumbency compared with 34.2 (25.4 and 43.5) pg/ml while supine]. Plasma atrial natriuretic peptide values fell after supine posture in only half the women and supine hypotension occurred in one subject. These studies demonstrate that upright and prolonged lateral recumbent postures significantly influence plasma atrial natriuretic peptide values during pregnancy, as they do in the nonpregnant state, but that supine posture does not alter plasma atrial natriuretic peptide values significantly. Posture must be carefully accounted for in any study of plasma atrial natriuretic peptide in pregnancy. (AM J OBSTET GYNECOL 1991;165:591-5.)

Key words: Atrial natriuretic peptide, pregnancy, posture, supine hypotension

Atrial natriuretic peptide is a peptide hormone synthesized and secreted by atrial cardiocytes. It is natriuretic, diuretic, and opposes the action of many vasoconstrictor substances.[1] In nonpregnant subjects, release of atrial natriuretic peptide is stimulated by atrial stretch,[2] intravascular volume expansion,[3] and oral salt-loading,[4] and is inhibited by upright posture,[5] venesection,[6] ultrafiltration,[7] and salt restriction.[4]

Thus atrial natriuretic peptide has been postulated to have a role in sodium and volume homeostasis and may be important in the regulation of maternal extracellular fluid volume and blood pressure changes during pregnancy. To date, studies of atrial natriuretic peptide in pregnancy have produced conflicting data with some finding basal atrial natriuretic peptide concentrations to be the same as in the nonpregnant state[8, 9] and others disputing this.[10, 11] Moreover, few studies have examined the regulation of this peptide's release during pregnancy, either in response to inhibitory or stimulatory maneuvers.[12-15] Therefore, we sought to examine the regulation of atrial natriuretic peptide in human pregnancy by determining the response of plasma atrial natriuretic peptide to upright, lateral recumbent, and supine recumbent postures, maneuvers known to alter atrial filling.

Methods

Subjects. Third-trimester, normotensive, outpatient, primigravid women were recruited from our antenatal clinic and gave written informed consent. All had singleton pregnancies and were not taking medications other than iron or vitamin supplements. Nonpregnant women were recruited from the nursing and laboratory staff of the same hospital. All subjects were maintained on an unrestricted diet and attended our clinical research room between 10 AM and 2 PM for these studies. The upright posture and lateral recumbent study groups included pregnant and nonpregnant women, whereas the supine recumbent group consisted of pregnant women only. Each subject participated in only one study.

Clinical studies. In each study height and weight were recorded and subjects then voided. After 10 minutes of rest, blood pressure while sitting was recorded in the left arm as systolic and phase IV diastolic blood pressure in pregnant women and phase V diastolic

BP, Blood pressure.

Baseline (prestudy) data and blood pressure before and after changes in posture for pregnant and nonpregnant women in the three posture studies. Data are mean ± SD.

*$p < 0.001$, pregnant vs. nonpregnant.

†$p < 0.05$, pregnant vs. nonpregnant.

blood pressure in nonpregnant women. After 20 minutes in lateral recumbency blood was collected for estimation of hematocrit and plasma atrial natriuretic peptide concentrations.

Upright Posture Study. After 20 minutes in lateral recumbency, subjects remained ambulant for 2 hours and then blood pressure was remeasured and blood was collected for plasma atrial natriuretic peptide evaluation.

Lateral recumbency study. After the initial 20 minutes of lateral recumbency blood was collected as described in this article and then subjects remained in this position for an additional 60 minutes. Blood was collected for remeasurement of plasma atrial natriuretic peptide at this stage.

Supine recumbency study. After 20 minutes in lateral recumbency, pregnant women turned to the supine position for another 20 minutes before the blood pressure and plasma atrial natriuretic peptide were remeasured. In a separate group of five patients, the period of supine posture was prolonged to a total of 2 hours and blood was collected at 30-minute intervals for measurement of plasma atrial natriuretic peptide. Fetal lie and subsequent birth weight were recorded for all participants in this study.

Laboratory measurements. Five milliliters of blood for estimation of plasma atrial natriuretic peptide was collected into a chilled tube that contained ethylenediaminetetraacetic acid (1 mg/ml) and Trasylol aprotinin preparation (50 IU/ml, Bayer) and kept on ice. This was centrifuged at 4°C at 3200 rpm for 15 minutes and the plasma was stored at − 70° C until assay. Plasma atrial natriuretic peptide was determined by radioimmunoassay (Immuno Technology Service Production B.V., The Netherlands) after extraction on C-18 silica columns (Baker) based on the method of Hartter et al.[16] The sensitivity of the assay was 0.8 pg/tube (2.0 pg/ml) and the intraassay and interassay coefficients of variation were 6.7% ($n = 12$) and 9.0% ($n = 6$), respectively. The recovery of synthetic atrial natriuretic peptide added to plasma was 110% for between 50 to 100 pg/ml and 93% for 25 pg/ml. No corrections for recovery were made. Hematocrit value was determined by an automated Coulter counter.

Statistics. Differences between groups were analyzed with the Mann-Whitney test and within groups by the Wilcoxon rank-sum test. Results are expressed as median and 25th and 75th percentiles for atrial natriuretic peptide data and as mean and SD for other data.

Results

Baseline (prestudy) data (Table I). There were no significant differences in the mean age, height, weight, blood pressure, basal plasma atrial natriuretic peptide level, hematocrit value, or stage of gestation among the three groups of pregnant women. Pregnant women in the upright posture study were younger and heavier than their nonpregnant controls and hematocrit value was significantly reduced in pregnant women in both the upright and the lateral recumbency studies.

The median plasma atrial natriuretic peptide concentration for all pregnant subjects (collected after 20 minutes in left lateral recumbency) was 38.6 (25th percentile, 26; 75th percentile, 53.1) pg/ml, which was not significantly different from that of nonpregnant subjects [32.9 (27.9 and 47.8) pg/ml]. Basal plasma atrial natriuretic peptide levels did not differ significantly among the three study groups.

Upright posture study. Plasma atrial natriuretic peptide values decreased significantly from lateral recumbency

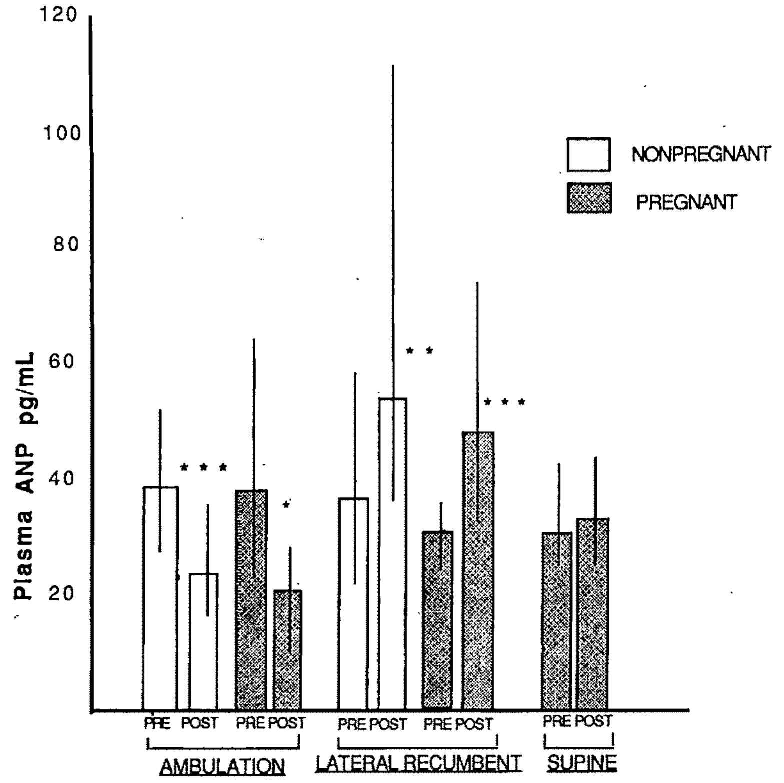

Fig. 1. Plasma atrial natriuretic peptide before and after 2 hours' ambulation, prolonged left lateral recumbency, and supine posture. Data are median and interquartile range. *ANP,* atrial natriuretic peptide. *One asterisk,* $p < 0.05$; *two asterisks,* $p < 0.01$; *three asterisks,* $p < 0.001$ preplasma atrial natriuretic peptide vs postplasma atrial natriuretic peptide.

to upright posture in both the pregnant and the nonpregnant groups (Fig. 1). The median decrease in plasma atrial natriuretic peptide level after 2 hours of upright posture was 11.3 (6.6 and 25.9) pg/ml in pregnant subjects and 10.6 (3.4 and 21.2) pg/ml in nonpregnant subjects.

Systolic blood pressure was not altered significantly by upright posture, although there was a significant increase in diastolic blood pressure in the pregnant group ($p < 0.01$) (Table I).

Lateral recumbency study. Basal plasma atrial natriuretic peptide values after 20 minutes were similar in the pregnant and nonpregnant women (Fig. 1). However, plasma atrial natriuretic peptide levels continued to increase significantly in both groups after a further 60 minutes in lateral recumbency (Fig. 1). The median increase in plasma atrial natriuretic peptide level was similar in pregnant [20.2 (1.0 and 43.8) pg/ml] and nonpregnant subjects [17.5 (8.7 and 44.9) pg/ml].

Supine recumbency study. Basal plasma atrial natriuretic peptide values were not altered significantly from values obtained during lateral recumbency after 20 minutes in supine recumbency in 21 pregnant subjects (Fig. 1). Closer analysis of these plasma atrial natriuretic peptide responses showed that only 12 of these women had a significant decrease in plasma atrial natriuretic peptide level after supine posture [from 35.3 (28.2 and 59.9) pg/ml to 26.2 (20.3 and 35.4) pg/ml ($p < 0.01$)] and the change in plasma atrial natriuretic peptide value was not related to basal plasma atrial natriuretic peptide.

In another five subjects, the period of supine recumbency was prolonged to 2 hours to ensure that this lack of uniform response was not a result of insufficient time spent in supine recumbency. This study demonstrated that the pattern of atrial natriuretic peptide response was always apparent by 30 minutes and that no further changes in plasma atrial natriuretic peptide levels occurred after this time.

Systolic and diastolic blood pressure levels were unaltered by supine posture (Table I) and only one patient experienced an asymptomatic fall in blood pressure from 112/68 to 88/62. Plasma atrial natriuretic peptide level in this patient fell from 28.7 to 16.9 pg/ml. There was a preponderance (70%) of right-lying fetuses, with the fetal head engaged in the pelvis in approximately 50%, and there was only one breech presentation. There was no correlation between fetal lie and plasma atrial natriuretic peptide response to supine posture. The birth weight for infants of women who had a decrease in plasma atrial natriuretic peptide level (3257 gm ± 486 SD) was similar to that of the remaining women (3306 gm ± 254 SD).

Comment

These studies demonstrate that in the late phase of pregnancy, plasma atrial natriuretic peptide value is reduced by upright posture and increased by prolongation of lateral recumbency to 80 minutes, responses that are similar to those of nonpregnant subjects. On the other hand, supine posture reduced plasma atrial natriuretic peptide values only in about half of the pregnant women studied.

It is evident that plasma atrial natriuretic peptide levels varied widely among pregnant women in this study, perhaps reflecting varied sodium intake, a factor known to alter plasma atrial natriuretic peptide values in nonpregnant[4] and pregnant women.[15] However, this study was primarily concerned with evaluation of the direction of change in plasma atrial natriuretic peptide induced by alterations in posture. On the basis of our understanding of atrial natriuretic peptide regulation in nonpregnant subjects, a fall in plasma atrial natriuretic peptide level was expected after upright posture inasmuch as cardiac catheterization studies have demonstrated that right atrial pressure falls by 4 to 7 mm Hg after upright posture.[17] During pregnancy the additional effects of compression of the iliac veins by the gravid uterus might enhance this reduction in atrial pressure during upright posture, although no similar hemodynamic studies have been made. This study confirms that physiologic inhibition of this hormone's release after upright posture is intact during pregnancy although there was no difference in the extent of the fall in plasma atrial natriuretic peptide level between pregnant and nonpregnant women.

Although other researchers have reported a fall in plasma atrial natriuretic peptide values after upright posture in nonpregnant subjects,[5, 18, 19] one study in pregnant women found no significant difference between plasma atrial natriuretic peptide level measured after 15 to 30 minutes seated and that measured after a subsequent 15 to 30 minutes in left lateral recumbency.[15] However, no previous study has examined the effect of prolonged lateral recumbency on plasma atrial natriuretic peptide in normal pregnancy. Our data show that plasma atrial natriuretic peptide level continues to rise significantly when lateral recumbency is extended from 20 to 80 minutes. Others have shown that in nonpregnant sodium-replete subjects, lying recumbent led to an increase in plasma atrial natriuretic peptide that peaked within the first 60 minutes.[20, 21] Others found no significant change in plasma atrial natriuretic peptide level over a 60-minute period of recumbency but this was probably because of the effect of rest before the commencement of the study, which masked the effect of recumbent posture on plasma atrial natriuretic peptide levels.[22] Our study did not determine the exact time for equilibration of plasma atrial natriuretic peptide after lateral recumbency although multiple early blood sampling as well as between 20 and 80 minutes would clarify this issue.

There are three possible explanations for our finding of an increase in plasma atrial natriuretic peptide level with prolonged recumbency. First, there may have been a gradual increase in atrial stretch as venous return increased from 20 to 80 minutes in recumbency although we did not measure central venous pressure directly in this study. Second, it is known that in nonpregnant subjects there is a lag from the time of atrial stretch until the plasma atrial natriuretic peptide level rises. This phenomenon has occurred both after intravenous volume expansion,[3] in which there was a 30-minute lag between peak central venous pressure and peak plasma atrial natriuretic peptide, and after head-down tilt where a 15-minute lag was demonstrated.[22] The explanation for this lag remains speculative but implies the involvement of an intermediate mediator of atrial natriuretic peptide release after atrial stretch.[23] A third explanation may be that prolonged recumbency reduces atrial natriuretic peptide clearance by the kidneys or liver. However, Gillies et al. have shown in males that recumbency usually increases the metabolic clearance rate of atrial natriuretic peptide when compared with sitting or standing[24] and this explanation therefore seems unlikely although there are no studies of the metabolic clearance rate of atrial natriuretic peptide during normal pregnancy.

To determine the relative importance of these three factors during pregnancy it would be necessary to perform simultaneous measurements of central venous pressure and plasma atrial natriuretic peptide during prolonged recumbency. However, on the balance of the available data for nonpregnant subjects, it seems most likely that the increase in plasma atrial natriuretic peptide value after prolonged recumbency in our study reflects a lag between the stimulus of atrial stretch and the peak in plasma atrial natriuretic peptide level.

Finally, supine posture led to a decrease in plasma atrial natriuretic peptide level in only half our third-trimester subjects, implying that a decrease in atrial stretch was perceived only in these subjects. The failure of atrial natriuretic peptide to fall in the remaining subjects was not a result of an inadequate period of supine posture, inasmuch as those who responded with a decrease in plasma atrial natriuretic peptide level did so within the first 30 minutes. Kerr et al. have performed manometric and radiologic studies in the late phase of pregnancy and found a high incidence of complete or partial obstruction of the inferior vena cava by the gravid uterus during supine posture.[25] Lees et al. subsequently studied eight women in the third trimester and showed a mean decrease in right atrial pressure of 3.6 mm Hg when the patient turned from lateral to supine recumbency.[26] Thus it might be anticipated that plasma atrial natriuretic peptide values would fall in all subjects after supine posture but this was not observed. Others believe that fetal position is the important determinant of the degree of caval compression that occurs during supine posture,[27] with engagement of the fetal head in the pelvis minimizing this effect. We found no correlation between fetal lie, birth weight, or gestation and the plasma atrial natriuretic peptide response. It seems most likely that the atrial natriuretic peptide response after supine posture represents a balance between increased venous return from the horizontal position and reduced inferior vena cava flow from uterine-fetal pressure. This must vary among pregnant women and it is therefore unlikely that all pregnant women will exhibit a decreased venous return and thus a fall in plasma atrial natriuretic peptide level after supine recumbency.

In summary, these studies have shown that the normal pregnant woman is able to inhibit the release of atrial natriuretic peptide after upright posture in a manner similar to that of nonpregnant women. After prolonged recumbency in the lateral position there is an increase in plasma atrial natriuretic peptide level and this should be accounted for in studies of atrial natriuretic peptide during pregnancy, particularly when normotensive and hypertensive pregnant women are compared. Finally, plasma atrial natriuretic peptide levels fall in only 50% of pregnant women when the supine position is adopted, probably reflecting the fact that not all experience a fall in right atrial pressure with this maneuver. Overall, the ability to regulate plasma atrial natriuretic peptide after changes in posture is intact during the late phase of normal pregnancy.

We thank Sr. Delma Adsett for assistance with the clinical studies and Mrs. Beryl Smith for her assistance.

Single and multiple administration of a new triphasic oral contraceptive to women: Pharmacokinetics of ethinyl estradiol and free and total testosterone levels in serum

Wilhelm Kuhnz, PhD, Durda Sostarek, Christiane Gansau, Tom Louton, PhD, and Marianne Mahler, MD
Berlin, Germany

Ethinyl estradiol is part of almost every combined oral contraceptive, and its pharmacokinetic characteristics have been thoroughly investigated in numerous studies. However, little is known about its pharmacokinetics during long-term administration, as compared with single-dose administration. In this study 10 women received a triphasic formulation that contained ethinyl estradiol together with the progestin gestodene over one treatment cycle. Mean area under the curve values of ethinyl estradiol were significantly higher on the last treatment day, as compared with the corresponding values obtained from the same women after single-dose administration. However, the observed increase in area under the curve was within the range of pharmacokinetic accumulation, to be expected on the basis of dosing interval and terminal half-life. Another point of interest was the effect of the triphasic preparation on testosterone concentrations in serum. Both total and free testosterone levels were suppressed by about 60% as compared with pretreatment values, and there was no correlation with corresponding sex hormone–binding globulin levels in the serum. (AM J OBSTET GYNECOL 1991;165:596-602.)

Key words: Pharmacokinetics, ethinyl estradiol, chronic administration, testosterone

Gestodene is a new synthetic progestin that, in combination with ethinyl estradiol, is part of a monophasic and a triphasic oral contraceptive. The pharmacokinetics of gestodene after single and multiple administration of the monophasic formulation has been investigated in several clinical studies.[1-3] The pharmacokinetics after single and multiple administration of the triphasic formulation has been reported previously.[4] In this communication the pharmacokinetics of ethinyl estradiol is presented. It was the aim of this study to compare basic pharmacokinetic parameters of ethinyl estradiol in individual subjects after single-dose administration with the corresponding parameters obtained during a complete treatment cycle. In particular, it was of interest to see whether there was an accumulation of ethinyl estradiol in the serum during long-term treatment. In addition, effects of the triphasic formulation on total and free testosterone concentrations were investigated. Since testosterone binds to sex hormone–binding globulin with a high affinity, another aim of this study was to assess any effect of changes in sex hormone–binding globulin concentrations during treatment on total and free testosterone levels in the serum. This could be of interest because reduced free testosterone concentrations could be responsible for a reduction of androgen-dependent side effects.

Material and methods

Study design. The study was designed as an open investigation on 10 healthy women, whose demographic data are presented in Table I. The women had normal biphasic cycles and had not used oral contraceptives for at least 2 months before they participated in the study. All women underwent a thorough physical and gynecologic examination, and informed consent was obtained before their participation.

The women received a single, coated tablet of the triphasic formulation, which contained 0.1 mg gestodene together with 0.03 mg ethinyl estradiol, on day 21 of a pretreatment cycle. Blood samples (5 ml) were taken after an overnight fast, before drug administration, and 0.5, 1, 1.5, 2, 4, 6, 8, 10, 12, 24, 48, and 72 hours after drug intake. A standardized breakfast was served 2 hours after treatment.

After a washout period of 7 days, in a second part of the study, the same women received the following triphasic formulation during a whole cycle: days 1 to 6, 0.05 mg gestodene together with 0.03 mg ethinyl estradiol; days 7 to 11, 0.07 mg gestodene together with 0.04 mg ethinyl estradiol; days 12 to 21, 0.1 mg gestodene together with 0.03 mg ethinyl estradiol.

Blood samples (5 ml) were taken after an overnight

fast on days 2 and 7 before and 0.5, 1, 1.5, 2, 4, 6, 8, 12, and 24 hours after drug administration and on day 21 before and 0.5, 1, 1.5, 2, 4, 6, 8, 12, 24, 48, 72, and 96 hours after drug intake. A standardized breakfast was served 2 hours after treatment on days 2, 7, and 21.

Additional blood samples were obtained on days 5, 10, 12, 14, 16, 18, and 20 in the morning, before drug administration. All blood samples were kept at 4° C until coagulation; the serum was separated and stored at −20° C until analysis.

Analytic determinations

Determination of ethinyl estradiol: Ethinyl estradiol was measured by a specific radioimmunoassay in all serum samples in duplicate, after an extraction of 0.3 ml serum with diethyl ether. The recovery of the extraction was >90%. Ethinyl estradiol-6,7-^3H (specific activity, 2.2 TBq/mmol; New England Nuclear) was used as tracer; radiochemical purity was >98%. The antiserum (Schering) was obtained by immunization of rabbits with the immunogen ethinyl estradiol-6β-carboxymethyloxime-bovine serum albumin; the final dilution was 1:400,000 in the assay. Details on the specificity of the antiserum are described elsewhere.[5] Extracts from serum samples were dissolved in buffer, antiserum and tracer (5000 counts/min) were added, and the mixture was incubated at 4° C for 16 hours. Bound and free steroids were separated by charcoal treatment, analogous with published procedures.[6] The sensitivity of the standard curve was about 3 to 4 pg ethinyl estradiol per tube, and the lower limit of quantitation was 15 pg/ml. Interassay precision ($n = 5$) was determined with three different control samples, containing ethinyl estradiol 50, 100, and 200 pg/ml plasma, respectively. Experimentally measured concentration values were 56.6 ± 6.0, 120.6 ± 9.1, and 217.6 ± 19.4 pg/ml, respectively. The coefficients of variation of interassay precision were 10.6%, 7.5%, and 8.9%, respectively. Deviations of measured from nomimal values were 13.2%, 20.6%, and 8.8%, respectively.

Other parameters. Total and free concentrations of testosterone and sex hormone–binding globulin and transcortin concentrations in the serum were determined radioimmunologically with commerically available assay kits: total and free testosterone, by solid-phase radioimmunoassays (Coat-A-Count, Diagnostic Products Corporation, Los Angeles), sex hormone–binding globulin, by an immunoradiometric assay (SHBG-IRMA-Count, Diagnostic Products Corporation, Los Angeles); and transcortin, by a radioimmunoassay (IRE Medgenix, Fleurus, Belgium).

Two quality control samples, representing low and high concentrations of the analyte, respectively, were included in each assay and measured in duplicate. Deviation of experimentally measured concentrations from nominal values was ≤16% for all analytes and interassay precision was <10% (coefficient of variation) for total and free testosterone determinations and <15% (coefficient of variation) for sex hormone–binding globulin and transcortin. The lower limits of quantitation were 0.1 ng/ml and 0.2 pg/ml for total and free testosterone, respectively. For sex hormone–binding globulin and transcortin the lower limits of quantitation were 0.5 mmol/L and 0.25 μg/ml, respectively.

Pharmacokinetic and statistical evaluation. Peak serum ethinyl estradiol concentrations and their time points were given as determined. The area under the serum versus time curve was calculated according to the trapezoidal rule. Rate constants of the disposition of ethinyl estradiol in serum and half-lives of its disposition were calculated by means of regression analysis of the logarithm of concentration of the terminal phase (range; 4 to 24 hours after administration). The accumulation factor (R) was calculated as follows:

$$R = \frac{1}{1 - e^{\frac{-\ln 2}{t_{1/2}}\tau}}$$

where $t_{1/2}$ = terminal half-life and τ = dosing interval. Target variables of ethinyl estradiol used for statistical evaluation were areas under the serum versus time

Table II. Concentration of ethinyl estradiol in sera of 10 women after single-dose administration of coated tablet containing 0.1 mg gestodene and 0.03 mg ethinyl estradiol

Sampling time	*Concentration of ethinyl estradiol (pg/ml, mean ± SD)*
Day 21	
0 hr	23.6 ± 13.6
0.5 hr	49.1 ± 27.6
1 hr	83.2 ± 33.6
1.5 hr	94.7 ± 30.4
2 hr	90.5 ± 28.5
4 hr	66.2 ± 12.4
6 hr	47.1 ± 11.8
8 hr	36.4 ± 11.8
10 hr	33.5 ± 8.6
12 hr	34.9 ± 22.0
Day 22, 24 hr	29.2 ± 8.7
Day 23, 48 hr	21.7 ± 10.0
Day 24, 72 hr	20.3 ± 8.7

curve at 0 to 4, 0 to 12, and 0 to 24 hours, obtained from the twenty-first day of the pretreatment and treatment cycles, respectively. The null hypothesis is that there is no difference between day 21 of the pretreatment cycle and day 21 of the treatment cycle with respect to the target variables cited. The alternative hypothesis is that there is a difference between day 21 of the two cycles with respect to a given target variable. With a sample size of 10 subjects, a type I error of 0.05, and a test power of $1 - \beta = 0.9$, a two-sided one sample t test would detect a difference of 1.15 σ.

The correlation coefficients between sex hormone–binding globulin and total free testosterone concentrations for each subject, respectively, were calculated.

Results

Pharmacokinetics of ethinyl estradiol after single- and multiple-dose administration. The time courses (mean ± SD) of the ethinyl estradiol levels observed in the sera of the 10 women after a single dose administration of 0.1 mg gestodene together with 0.03 mg ethinyl estradiol are presented in Table II. Maximum concentrations of 99.5 ± 27.5 pg/ml of ethinyl estradiol were observed after 1.9 ± 0.8 hours. Postmaximum ethinyl estradiol concentrations declined with a mean half-life of disposition of 11.2 ± 6.8 hours. The areas under the serum versus time curve at 0 to 4, 0 to 12, and 0 to 24 hours were 298.8 ± 78.6, 633.9 ± 127.1, and 1018.6 ± 246.1 pg · ml^{-1} · hr, respectively (Table III).

The time courses (mean ± SD) of ethinyl estradiol concentrations observed during the treatment cycle on days 2, 7, and 21 are presented in Table IV. Pharmacokinetic parameters of ethinyl estradiol were calculated on days 2, 7, and 21 of the treatment cycle. Concentration-dependent parameters (peak serum concentration, area under the curve) of ethinyl estradiol were somewhat higher on day 7, probably reflecting the higher dose (0.04 mg) administered (Table III).

On day 21, maximum concentrations of 139.7 ± 40.3 pg/ml were observed 1.6 ± 0.3 hours after administration, and the mean terminal half-life of disposition was 10.8 ± 3.0 hours. Values for the area under the serum versus time curves at 0 to 4, 0 to 12, and 0 to 24 hours were 426.6 ± 100.9, 937.6 ± 193.5, and 1407.0 ± 305.5 pg · ml^{-1} · hr, respectively. The corresponding differences with respect to the initial values on day 21 of the pretreatment cycle were 128 ± 100, 303 ± 211, and 388 ± 440 pg · ml^{-1} · hr, respectively. These were all significantly different from zero ($p < 0.05$).

Total and free testosterone, sex hormone–binding globulin, and transcortin. Sex hormone–binding globulin and transcortin concentrations in the serum before single-dose administration on day 21 of the pretreatment cycle were 90.3 ± 36.0 nmol/L and 37.4 ± 5.2 µg/ml, respectively. On day 21 of the treatment cycle sex hormone–binding globulin and transcortin levels were 198.8 ± 52.0 nmol/L and 84.9 ± 11.4 µg/ml, respectively (Table V).

Mean total and free concentrations of testosterone obtained after single-dose administration and throughout the treatment cycle are presented in Table V. The average correlations (r) between sex hormone–binding globulin and total and free testosterone were 0.21 ± 0.21 and 0.35 ± 0.27, respectively, with a sample size of 10 subjects. As compared with day 21 of the pretreatment cycle, both total and free testosterone concentrations decreased markedly during the treatment cycle (Fig. 1).

Comment

Administration of the triphasic formulation containing gestodene and ethinyl estradiol over one treatment cycle resulted in a 220% elevation of sex hormone–binding globulin concentration as compared with the corresponding pretreatment levels in serum. A similar increase was reported previously for another formulation that contained both hormones at a fixed dose ratio.[3] Total and free testosterone concentrations decreased during treatment in an equal manner, and there was no correlation with corresponding sex hormone–binding globulin levels in the serum. On day 21 of the treatment cycle, an approximate 60% decrease of total and free testosterone concentrations as com-

pared with the corresponding values on day 21 of the pretreatment cycle was observed. The unbound fraction of testosterone did not change during treatment. The decrease in both total and free testosterone concentrations was therefore due to the impact of the triphasic formulation on the hypothalamic-pituitary-gonadal axis and reflects the decreased production rate of testosterone. A similar observation was reported recently[5] from a study with another gestodene-containing oral contraceptive (0.075 mg gestodene and 0.03 mg ethinyl estradiol). The authors also found a marked decrease by 50% to 70% in free testosterone, but only an approximate 20% to 30% suppression of total testosterone levels in serum. The different extent in suppression of free and total testosterone was attributed by the authors to the rise in sex hormone–binding globulin concentrations. Although similarly high sex hormone–binding globulin levels were reached in this study, both total and free testosterone levels were suppressed to the same extent and showed no correlation with the corresponding sex hormone–binding globulin concentrations.

The increase in transcortin serum levels observed in the present study was identical to the one described for the monophasic gestodene-containing formulation.[7, 8] Transcortin concentrations in the serum are a direct measure for the dose of ethinyl estradiol administered and as such are not influenced by the coadministered progestin. Similar increases have been reported for other formulations containing the same dose of ethinyl estradiol.[3, 10]

When the area under the curve values of ethinyl estradiol were compared on day 21 after a single dose and after multiple-dose administration of the triphasic formulation to 10 women, a significant increase was observed during long-term treatment, although with a considerable interindividual variation. Because ethinyl

*Single-dose administration.

estradiol is not bound to any significant extent to sex hormone–binding globulin,[11] the concomitant increase in sex hormone–binding globulin concentrations cannot account for this phenomenon. Increasing ethinyl estradiol levels during long-term treatment have already been described during clinical studies with other oral contraceptives.[10, 12, 13] One explanation for the increasing levels was seen in the enterohepatic circulation of this steroid,[12] which during long-term administration might eventually determine steady-state drug levels in the serum. However, the contribution of enterohepatic recirculation of ethinyl estradiol to the total area under the curve was found to be <10%.[14] Another possible reason was thought to be an impairment of hepatic metabolic capacity, caused by an irreversible interaction of ethinyl estradiol with cytochrome P-450 enzymes, which was demonstrated in in vitro experiments.[15] However, so far neither of these explanations has been substantiated. Thus a satisfactory and conclusive explanation for all the observations made in this context has yet to be found.

Another approach is to take into account that the accumulation of ethinyl estradiol in the serum is determined by the ratio of the terminal half-life and the dosing interval. The accumulation can be calculated when both parameters are known. The dosing interval is 24 hours; however, the terminal half-life is a highly variable parameter. A large interindividual variation in terminal half-life (8 to 48 hours) has been reported for ethinyl estradiol,[16] and accordingly one can expect a large variation in ethinyl estradiol-serum levels during long-term treatment. In some individuals who show long half-lives of ethinyl estradiol, an increase in trough levels will be observed, whereas in others with shorter half-lives trough levels will remain practically unchanged. This could account for the interindividual variation in ethinyl estradiol levels during a treatment cycle that was found in this study and also was reported by others.[13]

The half-life determination of ethinyl estradiol is a critical issue. In modern contraceptive formulations it is only administered in low doses of <50 μg/day, the lower limit of determination is usually reached 24 hours after administration. A terminal half-life of disposition longer than about 10 hours therefore cannot be determined with any accuracy, which is a limitation of most published half-life data of ethinyl estradiol, including those presented in this study. In two studies higher doses of ethinyl estradiol were administered,[6, 17] and concentrations in the serum could be measured up to 48 hours after administration. Thus a more reliable evaluation of the terminal half-life of ethinyl estradiol was possible, and mean half-life values of 13.1 and 23 hours, respectively, were reported.

A further complication is the occasional occurrence of a secondary peak in the concentration-time curve observed at about 10 to 12 hours after administration, which is attributed to the enterohepatic circulation of ethinyl estradiol.[14]

In addition to these experimental difficulties in the determination of half-lives of ethinyl estradiol, not only is there the already mentioned large interindividual variation in this parameter but also there is a similarly large intraindividual variation. This has been shown by others[18] and also could be demonstrated in this study. The coefficients of intraindividual variation of the terminal half-life of ethinyl estradiol were in the range of 6% to 40%, and those of interindividual variation were in the range of 19% to 61%.

On the basis of the provisional half-lives of ethinyl estradiol, determined in this study up to 24 hours after a dose, accumulation factors ranging from 1.27 to 1.35 can be calculated, depending on which of the half-life values (10.8 to 12.3 hours) is used. In other words, as compared with the area under the curve values of ethinyl estradiol determined after single-dose administration, an accumulation between 27% and 35% can be expected during long-term treatment. The experimentally determined area under the curve values at the end of long-term treatment were between 38% and 48% higher than corresponding values after a single dose, which is within the theoretical range. However, a correlation between individual terminal half-lives of ethinyl estradiol and corresponding increases in the area under the curve could not be shown, probably because of the above-mentioned limitations of accurate calculation of terminal half-lives after low-dose treatment with ethinyl estradiol. Although other factors, such as enterohepatic circulation or impairment of hepatic metabolic capacity, may possibly contribute to the increase in ethinyl estradiol concentrations observed during long-term treatment, it seems that the observed accumulation of ethinyl estradiol also could be explained by the relation of dosing interval and individual terminal half-life.

In conclusion, this study revealed that there was an increase in ethinyl estradiol concentrations in the sera of women during a treatment cycle with the gestodene-containing triphasic oral contraceptive. Similar observations have been reported previously with other contraceptive formulations containing either gestodene or other progestins in combination with ethinyl estradiol. Although some possible causes for the increase in ethinyl estradiol levels were discussed, further studies are required for a conclusive explanation. During treatment total and free testosterone concentrations in the serum were suppressed to the same extent, although sex hormone–binding globulin levels increased markedly during the treatment cycle. A differential effect on total and free testosterone concentration was not observed.

Oral tocolysis with magnesium chloride: A randomized controlled prospective clinical trial

Jean M. Ricci, MD, Seemanthini Hariharan, MD, Andrew Helfgott, MD, Karel Reed, RN, and Mary Jo O'Sullivan, MD
Miami, Florida, and Los Angeles, California

A prospective randomized clinical trial was conducted to assess the efficacy and safety of enteric-coated magnesium chloride (SLOW MAG) as an oral tocolytic agent. Seventy-five patients between 24 and 34 weeks' gestation who were treated with intravenous magnesium sulfate for a first episode of preterm labor were enrolled. After a 12-hour contraction-free period on intravenous therapy, patients were randomized by sealed envelope to one of three groups: group 1, SLOW MAG (535 mg every 4 hours); group 2, oral ritodrine (20 mg every 4 hours); or group 3, no therapy (control). Patients receiving oral therapy were treated until delivery or completion of 36 weeks' gestation. No difference was found between groups with respect to time gained with the use of oral therapy or number completing 36 weeks' gestation. Therapy with enteric-coated magnesium chloride was associated with significantly fewer side effects (20%) as compared with ritodrine (48%) ($p < 0.01$). Our results suggest that compared with ritodrine, enteric-coated magnesium chloride is as effective in prolonging pregnancy and preventing recurrent preterm labor. However, neither enteric-coated magnesium chloride nor ritodrine appeared to be any more effective in the prevention of preterm delivery than observation alone. (AM J OBSTET GYNECOL 1991;165:603-10.)

Key words: Preterm labor, oral tocolysis, magnesium chloride, ritodrine

Prematurity is the leading cause of perinatal mortality in the United States, and the prevention of preterm delivery remains a major goal in obstetrics. Although a number of drugs are used as tocolytic agents in the United States, the effectiveness of these agents in the prevention of preterm delivery is questionable.[1-3] In particular, the role of oral tocolytic agents after successful intravenous therapy is controversial, inasmuch as their efficacy has not been determined.

Many investigators advocate parenteral magnesium sulfate for initial tocolysis because of its reported efficacy and minimal side effects compared with other tocolytic agents.[4-7] At The University of Miami/Jackson Memorial Medical Center, magnesium sulfate is routinely used for initial tocolysis. The dilemma frequently encountered is what if any oral tocolytic agent should be given once premature labor is arrested with parenteral magnesium sulfate. Typically at our institution, patients received the β-adrenergic receptor agonist ritodrine, which carries the same potential for side effects as its intravenous counterpart.[4-7] In addition, it is expensive, with a typical cost to the patient of $210 per week. Because of poor compliance, we therefore sought another agent that would be better tolerated and less costly until the issue of whether oral tocolytic agents were efficacious was resolved.

Historically, oral magnesium salts have not been used because of their known potential for causing gastrointestinal side effects. An enteric-coated form of magnesium chloride (SLOW MAG, Searle & Co., Chicago) is available for use in the United States as a magnesium supplement. SLOW MAG is well-tolerated in nonpregnant patients without the untoward effects typically found with magnesium salts.[8] Each delayed-release tablet of SLOW MAG provides 64 mg (5.26 meq) of elemental magnesium as 535 mg magnesium chloride hexahydrate ($MgCl_2 \cdot 6H_2O$). SLOW MAG is relatively inexpensive (100 tabs for $8.95) with a speculated cost when taken as a tocolytic agent of $2.50 per week. Interest in magnesium as an oral tocolytic agent has recently evolved; however, few clinical trials have been conducted to assess efficacy. A recent study with oral magnesium gluconate showed a relative lack of side effects.[9] However, its efficacy as a tocolytic agent was suggested but not proved.[9] This is the first prospective controlled randomized clinical trial that uses SLOW MAG to assess its efficacy and safety as an oral tocolytic agent.

Material and methods

At the University of Miami/Jackson Memorial Medical Center, intravenous magnesium sulfate is the first-line tocolytic agent used for all eligible patients admitted with a diagnosis of preterm labor. Preterm labor is defined as either: (1) an initial pelvic examination of 2 cm dilatation in conjunction with two or more contractions per 10 minutes of at least 30 seconds in duration or (2) a change in cervical examination by the same examiner over a 1-hour period in conjunction with two contractions or more per 10 minutes of at least 30 seconds in duration. Gestational age is determined by last menstrual period, early examination, and ultrasonography when available. Ultrasonography is performed on admission to rule out anomalies, confirm dates, and obtain an estimated fetal weight.

Patients excluded from initial intravenous tocolysis with magnesium sulfate are those with any of the following: (1) cervical dilatation ≥4 cm, (2) ruptured membranes, (3) obstetric hemorrhage, (4) chorioamnionitis, (5) preeclampsia, (6) eclampsia, (7) fetal death, or (8) lethal congenital anomaly. Magnesium sulfate is administered as a 4 gm intravenous bolus over 20 minutes, followed by a 2 gm/hour infusion. Serum magnesium levels are obtained before bolus, and then every 6 hours while on intravenous therapy and are not allowed to exceed a level of 8 ng/dl. Infusion rates are adjusted to achieve cessation of contractions, with the maximum infusion rate used being 4 gm/hour. Once contractions have ceased, patients are maintained on a constant infusion of magnesium sulfate for a 12-hour contraction-free period.

Between July 6, 1988, and June 2, 1989, tocolysis was successful with intravenous magnesium sulfate therapy for a first episode of preterm labor on the basis of the above criteria in 75 patients with singleton pregnancies between 24 and 34 completed weeks' gestation who were enrolled in this prospective clinical trial. This study was approved by the Human Subjects Committee at the University of Miami School of Medicine before its initiation. After a 12-hour contraction-free period with intravenous magnesium sulfate therapy, and after giving informed consent, patients were randomized by sealed envelope to one of three groups. Patients in group 1 received 10 mg of oral ritodrine every 2 hours for 24 hours, with the first dose given 30 minutes before discontinuation of the intravenous magnesium sulfate. After the first 24 hours, the ritodrine was changed to 20 mg every 4 hours. Patients in group 2 received one tablet (535 mg) of SLOW MAG every 4 hours, with the first dose given 30 minutes before discontinuation of intravenous magnesium sulfate. Patients in group 3 (observation only) did not receive oral medication, and their intravenous magnesium sulfate infusion was discontinued approximately 30 minutes after randomization. Regardless of group, all patients were observed on the antepartum ward for 48 hours before discharge and were taught the clinical signs and symptoms for preterm labor. All patients were discharged when stable and followed up weekly in a specially designed preterm birth prevention clinic. At each visit the patients were questioned regarding the presence of uterine contractions, low back pain, pelvic pressure, or discharge and were reeducated on the signs and symptoms of labor. Cervical examinations were done at each visit and the patients were monitored for 1 hour with an ambulatory tocodynamometer. The examining physician was blinded to the results of this monitoring until all patients in the study were delivered of infants. All patients were questioned during their clinic visits regarding potential side effects of oral therapy (chest pain, palpitations, tachycardia, headache, fatigue, nausea, vomiting, diarrhea, nervousness). Pulse rate was monitored in all patients. Those who received oral therapy were treated until completion of 36 weeks' gestation or until delivery. Serum magnesium levels were obtained 24 hours after cessation of intravenous magnesium sulfate therapy in all patients. Serum magnesium levels were also obtained weekly from the women who received SLOW MAG.

Patients with recurrent preterm labor were readmitted to the hospital. If the patient still met the defined criteria for intravenous tocolysis at our institution, then intravenous magnesium sulfate therapy was reinstituted. The choice of continued therapy with an oral tocolytic agent was then left to the discretion of the primary physician in attendance.

Among the three groups, we compared time gained in utero, time to and incidence of recurrent preterm labor, and percentage who were delivered of infants after 36 completed weeks' gestation. Time gained in utero was defined as time attributable to the patient's primary assigned therapy, excluding any further time gained in those who had recurrent preterm labor and who again had successful tocolysis. This was done to exclude the possibility of adding bias to the data. Tolerance of the two oral therapies was compared by assessing the incidence, type, and severity of the associated side effects. An analysis of the demographics of the study population was done. Neonatal outcome variables studied included birth weight, gestational age at delivery, Apgar scores, morbidity, and mortality. Serum magnesium levels were compared among groups. Data were analyzed by one-way analysis of variance, the Student t test, χ^2 test, Fisher's exact test, and linear regression as appropriate. A p value of <0.05 was considered significant.

Results

Twenty-five patients were enrolled in each group between July 6, 1988, and June 2, 1989, all of whom were delivered of infants by July 15, 1989. All patients were

of low socioeconomic status. No significant differences were found in maternal age, parity, or race among the three study groups (Table I). Although not statistically significant, more mothers in the SLOW MAG (36%) and ritodrine (28%) groups gave a history of preterm labor with a previous pregnancy than those in the observation group (20%). There was no difference in admitted history of tobacco or substance abuse among groups.

The groups were similar with respect to mean gestational age and cervical dilatation at the onset of preterm labor tocolysis (Table II). No difference was noted in the mean gestational days gained between groups whether considering total days gained (intravenous therapy plus oral therapy) or days gained with oral therapy alone. There was a trend toward more recurrent preterm labor and delivery before completion of 36 weeks' gestation in the observation group compared with the ritodrine and SLOW MAG patients. For patients with recurrent preterm labor, the mean number of days until the recurrence was similar among groups. As illustrated in Fig. 1, no difference occurred among groups in percentage of patients who achieved a 2-, 7-, or 14-day delay in delivery.

Because of a wide range of days gained in each group, we analyzed the data to identify whether cervical dilatation at initial diagnosis of preterm labor affected days gained. Each group had a similar number of patients dilated >2 cm at diagnosis (Table III). Time gained was not significantly different among the groups at >2 cm dilatation, and there was no difference between groups at <2 cm dilatation. However, within the groups, linear regression analysis revealed a negative association between time gained and cervical dilatation at the onset of therapy in the observation group ($r = -0.51$, $p = 0.01$) but not in the SLOW MAG ($r = -0.41, p = 0.05$) or ritodrine groups ($r = -0.32$, $p = 0.12$). The incidence of recurrent preterm labor was not statistically significantly different among groups, regardless of cervical dilatation. However, within all groups patients dilated >2 cm at diagnosis accounted for a higher proportion of recurrent preterm labor.

Thirty-seven of the 75 patients (49%) had a second episode of preterm labor. Of these, 26 were seen in active labor >4 cm dilated and four had premature rupture of membranes (PROM), laboring and delivering spontaneously within 3 days of admission. Tocolysis was successful a second time with intravenous magnesium sulfate therapy in the remaining seven pa-

	Total (contractions/hr)	*Term (contractions/hr)*	*Preterm (contractions/hr)*
SLOW MAG	6.8 ($N = 14$)	8.4 ($N = 8$)	4.7 ($N = 6$)
Ritodrine	4.4 ($N = 5$)	4.0 ($N = 2$)	4.7 ($N = 3$)
Observation	5.9 ($N = 13$)	7.9 ($N = 7$)	4.5 ($N = 6$)

tients. No patient had more than one episode of recurrent preterm labor.

Sixty-four percent (48/75) of the total study population were monitored for at least 1 hour during their weekly clinic visits. Of these, 16 patients were in the SLOW MAG group, 14 patients were taking ritodrine, and 18 patients were in the observation group. The remaining 27 patients were not monitored, primarily because of delivery before their clinic visit. Technical difficulties as well as noncompliance with clinic visits also made a small contribution. For those monitored, the mean number of strips per patient was 3.48 with a fairly even distribution among groups. Monitoring strips done within 7 days of delivery were available in 32 patients (43%). No difference was found among the three groups in the number of contractions per hour present within 7 days before delivery, whether considering all patients or only those who were delivered of infants before completion of 36 weeks' gestation (Table IV). Although not representative of the whole study population, in the subset of data available monitoring appeared to be of no benefit in predicting which patient was at risk of a recurrence in any of the three groups.

While receiving oral therapy in the hospital and on each weekly clinic visit, the patients who received SLOW MAG and ritodrine were questioned with regard to potential side effects from the medication. Patients who took ritodrine had significantly higher resting pulse rates (96.85 ± 10.73) than did those who took SLOW MAG (82.53 ± 4.73) or no therapy

‡$p < 0.05$.

(85.15 ± 4.86) ($p < 0.005$). Table V illustrates the side effects that the patients experienced with their respective medications. Twenty percent (5/25) of patients who took SLOW MAG had side effects, as compared with 48% (12/25) who received ritodrine ($p < 0.01$). Side effects were severe enough to result in discontinuation of ritodrine in one patient because of nervousness and palpitations. In the SLOW MAG group, two patients discontinued the medication, one because of diarrhea and one because of persistant fatigue. It is notable that the latter patient's complaints of fatigue persisted for the duration of her pregnancy.

Serum magnesium levels were compared among groups before intravenous magnesium sulfate, 24 hours after discontinuation of intravenous magnesium sulfate, and weekly in patients taking SLOW MAG (Table VI). There was no significant difference between preintravenous magnesium levels among the three groups. Patients taking SLOW MAG had significantly higher magnesium levels (2.00 ± 0.44) than those of the other two groups. The mean magnesium level for patients taking SLOW MAG from follow-up weekly levels was 1.80 ± 0.16.

The neonatal outcome variables (Table VII) revealed no difference in mean gestational age at delivery or birth weight among groups. The groups were similar with respect to 5-minute Apgar scores, neonatal morbidity and mortality, and hospital stay.

Comment

It is well recognized that intravenous magnesium sulfate is efficacious and safe for initial tocolysis.[4, 5, 10] The purpose of this study was to observe whether orally administered enteric-coated magnesium chloride (SLOW MAG) in patients with arrested preterm labor would prolong gestation and prevent recurrent preterm labor.

In general, studies evaluating the effectiveness of tocolysis in decreasing the rate of preterm birth have shown inconsistent results.[11, 12] In a metaanalysis of 16 controlled clinical trials, initial tocolysis with β-sympathomimetic drugs was found to have a marginal effect in decreasing the preterm delivery rate, and no effect on the perinatal mortality rate.[13] It appears that initial tocolysis provides a short-term delay in delivery, with the best effect in the first 24 hours. One should not expect more than a 48-hour delay in delivery.[14] Of patients who receive only initial therapy, whether with a β-sympathomimetic or magnesium sulfate, 50% will be delivered of infants within 48 hours of discontinuation and no patients should be expected to achieve more than a 7-day delay in delivery.[2]

An oral agent for maintenance therapy has become generally accepted in the United States. Three controlled clinical trials designed to assess the efficacy of continued oral therapy exist in the literature. In the study by Creasy et al.[15] in which preterm labor was arrested with intravenous ritodrine and patients were then randomized to oral ritodrine or placebo, there was no difference in mean gestational age at delivery or in number of days gained after treatment began. An increased number of recurrent preterm labor episodes was, however, found in the placebo group (2.7 vs 1.1), with a fourfold shorter time interval to recurrence than in the ritodrine group, although the exact number of patients who actually had a recurrence in either group is not described. Merkatz et al.[16] reported that patients who received intravenous ritodrine were more likely to achieve a term delivery when continued on oral ritodrine as compared with placebo (52% vs 38%). Patients in whom initial tocolysis was achieved with intravenous alcohol and who then received terbutaline or placebo showed a significant increase in days gained and birth weight in the terbutaline group as reported by Brown and Tejani,[17] but recurrent preterm labor was not discussed specifically. Other investigators have advocated prophylactic oral tocolytic therapy, particularly with β-sympathomimetic drugs, although these studies were not controlled and the effect of the oral therapy per se is difficult to ascertain.[6, 18]

Recently agents other than β-sympathomimetic drugs have been investigated for their oral tocolytic potential. A nonrandomized uncontrolled comparison of magnesium gluconate versus oral ritodrine found equivalent results in the percentage that achieved term delivery (80% for both) and the incidence of recurrent preterm labor (magnesium gluconate 28% vs ritodrine 28%).[19] A criticism of that study was the absence of a control group. In addition, cervical change was not required as part of the definition of preterm labor. Because the success rates reported were higher than those reported by others and ourselves, it is probable that a

large proportion of the patients were never actually in preterm labor.

This study is the first controlled investigation of continued tocolytic therapy with an oral magnesium salt of which we are aware. We found no difference in the ability of SLOW MAG or ritodrine to prolong pregnancy or to achieve delivery after completion of 36 weeks' gestation. Moreover, neither of these two agents was any more effective than close observation alone. In comparison with other studies, we achieved a similar outcome in those who received therapy but a better outcome in our observation group.[15, 16] It has been suggested that oral ritodrine as maintenance therapy is effective in the prevention of recurrent preterm labor.[15, 16] In this study, SLOW MAG proved to be as effective as ritodrine. Our observation group had a longer time to relapse and less recurrences in comparison with the placebo group of prior studies.[15, 16] However, as compared with the ritodrine (48%) and magnesium (44%) groups, there was a trend for more patients in the observation group to have a recurrence of preterm labor (56%). Whether this is a clinically important difference is questionable. Our sample size was not large enough to detect subtle differences in treatment effect. Because the ultimate outcome in all three groups with respect to birth weight, multiple measures of neonatal morbidity, mortality, and hospital stay was the same, it appears this difference had no clinical significance.

A clear difference in time gained in all three groups was observed depending on the patient's cervical examination on admission. Those patients initially dilated >2 cm gained less time. The best success rates with intravenous magnesium sulfate have been reported when cervical dilatation is <2 cm.[4, 5, 10] Those who received intravenous magnesium sulfate and oral ritodrine when initial cervical dilatation is <2 cm can be expected to have a 48-hour delay in delivery 80% of the time, but this falls to 50% if the cervix is dilated >2 cm.[4, 5, 10] From this study, patients who were dilated >2 cm also had a higher incidence of preterm labor recurrence. On linear regression analysis there was an association between the first cervical examination and time gained in the observation group, the greater the dilatation, the less time gained. This association, however, was not seen in the ritodrine or SLOW MAG groups. Perhaps oral therapy is best indicated for those patients whose initial examination shows >2 cm dilation.

It has been suggested that monitoring uterine activity may be beneficial for patients at risk of recurrent preterm labor.[20, 21] In a study of low-risk singleton gestations, on weekly 1-hour uterine tocodynometry, more than six contractions per hour indicated a high risk of preterm labor.[22] Others have found four contractions per hour predictive of impending preterm labor.[23] We attempted to monitor patients weekly for 1 hour to determine whether this would help predict which patients were at higher risk of recurrence. Monitoring strips performed within 7 days of delivery were available in only 43% of the study population. Of those with recurrent preterm labor, strips were available for review of 15 patients evenly distributed across the three groups. The same number of contractions per hour occurred among groups and actually fewer contractions per hour were found than in those patients delivered at term. The benefit of uterine monitoring is controversial. Programs that use it also provide frequent nursing contact and teaching. It may be the combination of patient education and support that contribute to a decrease in preterm birth rather than monitoring alone.[24] In this study, the observation group had a better outcome than that of placebo groups in earlier studies. Perhaps this can be attributed in part to the educational program and close contact that our patients received.

We have shown that SLOW MAG is safe to use in pregnancy and is associated with minimal side effects. Those encountered with oral ritodrine were frequent and confirmed previous reports.[15] No serious consequences from either mode of therapy were encountered. It was necessary to discontinue SLOW MAG in two patients, one because of diarrhea and one because of fatigue. The latter persisted despite discontinuation of the drug. Lethargy as a result of the action of magnesium on the neuromuscular junction and striated muscle is a well-recognized complaint of patients who receive intravenous magnesium sulfate.[6] Given the difference in appearance of ritodrine and SLOW MAG, we believed it would be impossible to have a blinded or placebo-controlled study, therefore bias in the data is possible. Neither of the physicians who actually questioned the patients with regard to side effects (J. M. R. and A. H.) had a vested interest in the SLOW MAG product or knowledge of its potential side effects in the dose prescribed.

SLOW MAG therapy resulted in significant elevation in serum magnesium levels. The mean serum magnesium levels for all patients was on the low side of normal before receiving magnesium sulfate therapy. This has previously been described in patients with preterm labor.[5, 9] It is unknown what serum level of magnesium if any is required for effective oral tocolysis. With intravenous magnesium sulfate therapy, levels are obtained more for safety reasons rather than for therapeutic purposes, inasmuch as no correlation between efficacy and levels has been shown. The dose of SLOW MAG used provided 384 mg of elemental magnesium and mimics that used by Martin.[9, 19]

Given the results of this pilot study one can reasonably conclude that additional controlled clinical trials are needed to justify the continued use of oral tocolytic therapy in the United States. Until this is done, we believe that SLOW MAG offers an alternative to ritodrine for continued oral therapy in patients whose preterm labor has been arrested by intravenous therapy.

The effects of betamethasone on maternal cellular resistance to infection

Dean S. Cunningham, MD, PhD, and Edward E. Evans, MD

Portsmouth, Virginia

Antenatal administration of glucocorticoids is often used to facilitate fetal lung maturation in cases of prematurity; however, the effects of betamethasone on maternal immune function have not been established. Therefore maternal immune function was assessed with the use of in vitro techniques. Transient and incomplete suppression of the proliferative response to the T-cell mitogen phytohemagglutinin was demonstrated as early as 24 hours after administration of betamethasone. The magnitude and duration of suppression showed a corresponding increase with advancing gestational age, but these effects were not cumulative and were always short-lived (<72 hours). No such suppression of the B-cell mitogen lipopolysaccharide was detected. The nonspecific cellular resistance to infection of maternal monocytes was determined through coincubation with the facultative intracellular pathogen *Listeria monocytogenes*. Increased phagocytic activity with a normal bactericidal effect was measured in the cell preparations obtained from recipients versus nonrecipients of betamethasone. Taken together, these findings clearly show that both specific and nonspecific immune function are intact in the preterm gravid woman after administration of betamethasone and should allay concerns over its use for reasons of infection control alone. (Am J Obstet Gynecol 1991;165:610-5.)

Key words: Fetal lung maturity, preterm labor, corticosteroids, maternal immunity

True preterm labor[1] develops in approximately 7% of gravid women. Of concern is the lack of understanding regarding the cause of this entity, the oftentimes ineffective treatment modalities currently available, and the accompanying complications of preterm delivery that account for some 80% of all neonatal morbidity and mortality.[2]

In an attempt to obviate the respiratory compromise that afflicts the preterm infant, many obstetricians administer betamethasone to the pregnant woman when preterm labor has been arrested. Betamethasone is thought to increase the activity of choline phosphotransferase, thereby enhancing the production of fetal surfactant.[3] With the exception of maternal disorders that contraindicate the safe use of betamethasone (e.g., tuberculosis and peptic ulcer disease), complications of pregnancy per se (e.g., gestational diabetes and pregnancy-associated hypertension) should not limit its use.[4]

The purpose of this study was to further define the appropriateness of betamethasone use during pregnancy by determining its effect on maternal immune function at the cellular level and demonstrating whether the gravid woman is at increased risk for opportunistic infection.

Material and methods

Patients. The study population was limited to healthy gravid women with a singleton gestation who had first-trimester ultrasonographically confirmed dates between 28 weeks and 32 weeks 6 days of gestation and who met criteria for the diagnosis of preterm labor as described by Creasy and Herron,[5] that is, a minimum cervical dilatation of 2 cm and/or 80% effacement or cervical change accompanied by uterine contractions (four in 20 minutes or eight in 60 minutes). Excluded from the study population were those that had known maternal infection, cervical dilatation ≥ 4 cm at the time of presentation, known congenital anomalies, a lecithin/sphingomyelin ratio ≥ 2.0, or preterm premature rupture of the membranes. Written and verbal informed consent was obtained from all participants in an institution-approved protocol.

Subjects were entered into the study after presentation to the labor and delivery suite when the aforementioned criteria were met. If tocolysis with intravenous magnesium sulfate or subcutaneous terbutaline was successful for at least 2 hours and if delivery, in the judgment of the authors, was unlikely to occur in less than 24 hours, the subject was randomized to be a recipient or nonrecipient of betamethasone. A total of 86 patients were randomized into the study and 50 gestational age–matched patients who were not in labor served as controls. For those designated as recipients, 12 mg of betamethasone was administered intramuscularly and repeated after 12 hours; the drug was then given weekly until 32 completed weeks of gestation.

Peripheral blood processing. Venous blood was drawn from each study subject at the time of randomization and again 24, 48, 72, and 168 hours later. Peripheral blood mononuclear cells were obtained from heparinized (20 U/ml) peripheral blood by sedimentation[6] with Ficoll-Paque (Pharmacia, Piscataway, N.J.) leukocyte separation media. Purified peripheral blood mononuclear cells were washed three times in 50 volumes of complete culture medium by centrifugation at 1200 *g* at room temperature for 10 minutes. The complete culture medium was RPMI 1640 supplemented with 1 mmol/L glutamine, penicillin (100 U/ml), streptomycin (100 µg/ml), 25 mmol/L HEPES, 5×10^{-5} mol/L 2-mercaptoethanol, 12% fetal bovine serum plus 2% horse serum (Reheis Chemical Co., Kankakee, Ill.). Washed peripheral blood mononuclear cells were counted on a hemacytometer, resuspended in complete culture medium at a concentration of 5×10^6/ml, and placed on ice until use.

Monocyte-enriched cell preparations were produced with microexudate-coated tissue culture flasks as described by Ackerman and Douglas.[7]

Lymphoproliferative assay. Cultures were established in triplicate to assess mitogen-induced blastogenesis with peripheral blood mononuclear cells at a density of 1×10^5 per culture in a total volume of 1 ml (No. 3008 multiwell tissue culture plates, Falcon Plastics, Oxnard, Calif.) for 7 days, the last 18 hours of which were in the presence of tritiated thymidine (specific activity, 51 Ci/mmol/L; Research Products International Corp., Elk Grove, Ill.), and stimulated with 10 µg of phytohemagglutinin-P (Difco Laboratories, Detroit) or 25 µg of lipopolysaccharide (*Escherichia coli* 055:B5; Difco). Cultures were harvested onto glass fiber filters, and the incorporation of tritiated thymidine was determined by liquid scintillation spectrophotometry.

Bacteria. *Listeria monocytogenes* strain EGD (Trudeau Institute, Inc., Saranac Lake, N.Y.) was used. A log phase culture (approximately 2×10^8 bacteria per milliliter) was grown in tryptic soy broth and frozen at −20° C in 1 ml aliquots. Before assay the organisms were grown overnight in 5 ml of tryptose phosphate broth, isolated by centrifugation, and diluted in Hanks' balanced salt solution.

Phagocytic assay. The ingestion of *L. monocytogenes* by human monocytes was quantified as described by Czuprynski et al.[8] Briefly, 2.5×10^6 adherent monocytes, 2.5×10^7 bacteria, and 0.1 ml of 50% pooled AB-positive sera in a total volume of 1 ml of Hanks' balanced salt solution admixed in 12 × 75 mm plastic tubes in triplicate. The cultures were rotated in an end-over-end fashion for 30 minutes at 10 rpm at 37° C. After incubation, the cultures were washed three times in Hanks' balanced salt solution by centrifugation at 300 *g* for 10 minutes at 4° C. The cell preparations were centrifuged and treated with Diff-Quick stain (Dade Diagnostics, Aguada, Puerto Rico); intracellular bacteria were enumerated by means of light microscopy. The phagocytic index was calculated as the percentage of monocytes containing at least one bacterium multiplied by the average number of bacteria per positive monocyte.

Bactericidal assay. For measurement of bactericidal activity, admixtures of monocytes (2.5×10^6) and bacteria (2.5×10^6) were incubated as described and rotated for 3 hours at 37° C. Ten volumes of sterile distilled water was added to a sample of the admixture to lyse monocytes and release intracellular bacteria before incubation and again 3 hours later. The samples were plated and incubated, and colonies were counted 48 hours later. The percentage of bacteria killed was determined by dividing the number of bacteria present at 3 hours by the number of bacteria present at time 0.

Statistical analysis. Blastogenesis data were corrected for nonnormality by a square root transformation, and phagocytic and bactericidal data were normalized with an arc sine transformation before statistical evaluation by an analysis of variance and Dunnett's multiple comparison test.[9]

Results

Mitogen-induced blastogenesis of maternal lymphocytes was used to assess the effect of betamethasone on immune function. As shown in Table I, preterm labor, in and of itself, had no effect on T- or B-cell mitogenesis regardless of gestational age. Lymphocytes from patients with preterm labor treated with betamethasone were normally responsive to stimulation with the B-cell mitogen lipopolysaccharide; however, there was partial suppression of tritiated thymidine incorporation after stimulation with the T-cell mitogen phytohemagglutinin (Table I). Those hyporesponsive lymphocytes were affected as early as 24 hours after maternal treatment with betamethasone, and this effect persisted for at least an additional 24 hours (Table II).

Although the magnitude of suppression did not increase over the 72-hour measurement interval with any

cell source, lymphocytes obtained from patients at 28 or 29 weeks' gestational age were less affected than those obtained from patients at 30, 31, or 32 weeks (21% to 27% vs 47% to 56%; Table II). All blastogenic responses had normalized by 72 hours and were without further change in magnitude at 168 hours after treatment (Table II). The suppression detected was independent of cell density, length of stimulation, and dose of mitogen (data not shown).

Patients that had successful tocolysis at 28 to 31 weeks' gestation were candidates for repeat doses of betamethasone. The data in Table III indicate that suppression of blastogenic responsiveness was not cumulative, and the kinetics of affect were not altered (data not shown).

Because of the transient depression in T-cell-mediated immunity as determined by the blastogenic response to phytohemagglutinin of lymphocytes obtained from betamethasone recipients, monocytes were obtained from the same subjects and evaluated for resistance to infection with the facultative intracellular bacterium *L. monocytogenes.* The phagocytic index was shown to be enhanced as compared both with control subjects and with nonrecipients of betamethasone at all gestational ages tested (Table IV). These findings were strictly time dependent, peaking at 24 hours after administration of betamethasone with a return to normal levels by 48 hours. In contrast, no difference in bactericidal activity was evident in comparing monocytes derived from gestational age–matched controls and recipients and nonrecipients of betamethasone (Table V). Further, no additional differences in phagocytic indices or bactericidal activities were demonstrated with tests on monocytes obtained from those subjects with successful tocolysis versus those with failure of tocolysis (data not shown).

Comment

The overwhelming consensus of large collaborative trials in the United States and United Kingdom is that antenatal administration of betamethasone to gravid women in preterm labor (≥28 weeks and up to 32 to 34 weeks' gestation) results in a reduction in the incidence of neonatal respiratory distress syndrome.[10-12] Nevertheless, fewer than 50% of obstetricians use betamethasone for the infant at high risk for respiratory distress syndrome.[13] Betamethasone is not universally used for a variety of reasons: (1) its effect is proved only with successful tocolysis, which one cannot easily predict from patient to patient; (2) response to treatment differs with race, gender, and gestational age; (3) it is thought that the potential untoward side effects of the steroid include suppression of maternal immunity with a concomitant increase in maternal and neonatal infection rate.

The maternal immune response clearly changes during the course of pregnancy. Most notably, antibody-mediated immunity remains intact, whereas cell-mediated immunity is altered, presumably through shifts in T-cell subpopulations.[14] However, under normal circumstances it appears that pregnancy does not necessarily render the gravid woman immunocompromised.[15]

Despite the long-held traditional use of steroids for

immunosuppressive therapy, the immune system of humans is relatively resistant compared with animal models.[16] The extent and mechanism of action of corticosteroids on the immune response remain to be determined and the relative effects of different dosing regimens are unknown. It is likely that lymphocyte circulation, intrinsic function, and/or elaboration of soluble mediators are all potential targets of action, being affected 4 to 6 hours after a single dose and for up to 24 hours thereafter.[17]

For these reasons we set out to demonstrate what effect, if any, betamethasone administration has on maternal immune function. We confirmed the findings of others[18] that lymphoblast transformation is altered during gestation in a trimester-dependent fashion and that the administration of low doses of corticosteroids further exacerbates this effect on cell-mediated immunity, albeit transiently.

The effects of betamethasone appeared to dominate the T-cell population; therefore we utilized the well-accepted in vitro phagocytic and bactericidal assay of *L. monocytogenes* to evaluate the maternal resistance to infection on a cellular level. We showed increased phagocytic activity with normal bactericidal action in the recipients of betamethasone, which likely represents a compensatory response of monocytes to diminished T-cell activity. This in vitro analogue compares quite well with most other reports in the literature and our own findings, which showed no increase in maternal or neonatal infections in recipients versus nonrecipients of betamethasone (Cunningham DS, Evans EE. Unpublished data), but does differ with at least one study, which showed an increase in maternal infections after betamethasone administration.[19] A prospective comparison of the rates of neonatal sepsis, intraamniotic infection, and postpartum endometritis between recipients and nonrecipients of betamethasone needs to be done.

Recent studies have provided a rational impetus for the adjunctive use of betamethasone with neonatal surfactant[20] and thyrotropin-releasing hormone.[21] Because of this we must continue to document the safety and efficacy of betamethasone for fetal lung maturation. Our data support the safe use of betamethasone in patients in preterm labor with intact membranes, but there remains some concern whether this management scheme is appropriate in the patient in preterm labor with ruptured membranes. Using an approach similar to that in this study one could conceivably put this issue to rest.

We appreciate the thoughtful comments of Dr. Keith A. Hansen throughout the course of this project.

Vasopressin and operative hysteroscopy in the management of delayed postabortion and postpartum bleeding

Duane E. Townsend, MD, Solon D. Barbis, MD, and Roger D. Mathews, MD
Sacramento, California

Two women, one with refractory postabortion hemorrhage and the other with refractory postpartum hemorrhage, were managed with vasopressin, operative hysteroscopy, and a dilute vasopressin pack. Both patients had been treated by standard methods (i.e., dilation and curettage) and both were being prepared for a surgical intervention procedure. It was decided in both cases to try to slow the bleeding by injection of vasopressin paracervically and then performance of operative hysteroscopy. In both cases, the injection of dilute vasopressin paracervically when coupled with operative hysteroscopy was quite effective in determining the cause of the bleeding and was instrumental in avoiding major operative procedures. (Am J Obstet Gynecol 1991;165:616-8.)

Key words: Vasopressin, operative hysteroscopy

Delayed postabortion and postpartum hemorrhage is uncommon and consequently a problem seldom discussed in obstetrics and gynecology. In fact, there are no articles on extensive review that address the management of refractory delayed postabortion hemorrhage. Few articles have been devoted to delayed postpartum hemorrhage but the management of these patients usually consists of a suction or sharp curettage that when ineffective is followed by intrauterine packing, uterine artery ligation, or even hysterectomy. In some instances, recommendations for angiographic embolization are suggested when suction or sharp curettage is ineffective. Undoubtedly, most physicians would follow a similar approach for delayed postabortion hemorrhage. We have had the opportunity to manage two patients with vasopressin and operative hysteroscopy: one with a delayed refractory postabortion hemorrhage and the other with a delayed postpartum hemorrhage. Both patients were successfully managed and in both instances a major operative procedure that had been planned was avoided. The particulars of each case are presented in the hopes that other patients who are first seen with similar problems might benefit from a similar management scheme.

Case reports

Case 1. The patient was a 27-year-old, gravida 4, para 1, aborta 3 woman who underwent an uneventful outpatient suction curettage for pregnancy termination at 13 weeks' gestation. The procedure was uneventful, and the patient was discharged. Four days after surgery she began to note light bleeding and within a few hours bleeding became copious. She was hospitalized, given three units of packed blood cells, and then taken to surgery where she underwent a sharp curettage of the entire cavity; no tissue was obtained, and the bleeding was only minimally reduced. However, with bed rest as well as methylergonovine maleate, the bleeding subsided over the next 4 hours. She required one additional unit of blood before discharge. After being at home at virtual bed rest for 3 days, she again began to note red vaginal bleeding, which within 24 hours was bright red and profuse. She was taken to the emergency room, transfused with three units of packed blood cells, and then taken to the operating room in anticipation of a laparotomy with either hypogastric artery ligation or hysterectomy. However, before surgery it was decided to try to use the resectoscope along with a paracervical injection of dilute vasopression to determine whether this approach would be of any benefit in determining the cause of bleeding.

After induction of general anesthesia, the patient was placed in position and then prepped and draped in a sterile manner. A weighted speculum was placed in the vagina, and the cervix was firmly grasped with a single-tooth tenaculum. Bright red blood was briskly running out of the cervix. The uterus was firm and judged to be 6 weeks' gestational size. After exposing the vaginal fornices 5 ml of dilute vasopression solution (i.e., 20 units diluted in 30 ml of normal saline solution) was injected paracervically at the 3-o'clock and 9-o'clock positions and within 3 minutes the bleeding dramatically diminished. Then an Olympus 24 French single-channel resectoscope (Olympus Corp., Lake Success, N.Y.) with a wire loop electrode was inserted into the

6/1/30054

uterine cavity. Small clots were cleared with the use of full strength dextran 70 (Hyskon, Pharmacia Inc., Piscataway, N.J.) and the cavity was carefully inspected. A smooth lining was noted without any tissue. However, arterial bleeding was noted along the left uterine wall just above the internal os. The bleeding points were coagulated with a wire loop electrode at a setting of 100 W coagulation. Several additional oozing points that were noted in the fundus were also coagulated. The resectoscope was removed and then approximately 12 inches of 1-inch new gauze packing that had been soaked in the remaining dilute vasopressin solution was firmly packed into the uterus with a long smooth finger forceps. The patient was awakened and transferred to intensive care for observation. Cefazolin (Kefzol; Eli Lilly & Co., Indianapolis, Ind.) 500 mg intravenously every 8 hours and metronidazole (Flagyl; Schiapparelli Searle, Chicago, Ill.) 500 mg intravenously every 6 hours were started. The patient did not bleed through the pack, which was removed 18 hours after surgery. She was continued on bed rest for an additional 2 hours and was then ambulated. She had no further bleeding and was discharged home. Since discharge, which has been approximately 8 months, she has resumed light but normal menses without evidence of any endocrinologic problems.

Case 2. The patient was a 43-year-old, gravida 3, para 3 woman who had undergone a cesarean section at 33 weeks' gestation. She had previous uneventful pregnancies and came in with premature rupture of membranes. She went into labor within 12 hours of admission and because of marked deceleration of the fetal heart rate, a low transverse cesarean section was performed. Closure was in two layers with the use of 0 chromic suture. She was discharged in good condition on the third postoperative day. Twenty days after discharge she began to note intermittent dark red vaginal bleeding. She was treated with bed rest, which proved to be ineffective and within 24 hours the bleeding became bright red and profuse. She was taken to the emergency room where her hemoglobin was noted to be 6 gm. She was tranfused with 3 units of blood and taken to the operating room where a sharp curettage was performed. A moderate amount of tissue was obtained but had no impact on the bleeding. Hysteroscopy was attempted but because of the bleeding was ineffective. A decision was then made to perform a laparotomy with either hypogastric artery ligation or hysterectomy. However, before laparotomy a second decision was made to determine whether a paracervical injection of dilute vasopressin would slow the bleeding to permit reinspection of the uterine cavity with the use of the resectoscope. Within a few minutes after injection of dilute vasopressin (20 units in 30 ml of saline solution), 5 ml at the 3-o'clock and 9-o'clock positions, the bleeding slowed dramatically, and the resectoscope was inserted into the uterine cavity. With the use of sorbitol as the irrigant, several bright red bleeding points were noted on the posterior wall that were coagulated with a rollerball electrode at 100 W coagulation. Large amounts of tissue were present in the anterior fundus. With the use of a combination of a sharp curette and packing forceps, large amounts of placental tissue and amniotic membranes were obtained. After the uterus had been evacuated, the cavity was reinspected and additional bright red bleeding points were noted anteriorly. These were controlled with coagulation. Sixty inches of 1-inch new gauze cotton dressing that had been soaked in a dilute vasopressin pack with a concentration similar to that of the injection was firmly placed in the uterine cavity with a packing forceps. The patient was transferred to intensive care and observed overnight. She had no further bleeding, the pack was removed, and she was ambulated. She had no significant bleeding over the next 24 hours and she was then discharged. Since discharge more than 4 months ago, she has resumed normal menses.

Comment

These two cases show the potential benefit of the resectoscope along with the use of dilute vasoconstrictors and packing in the control of delayed refractory postabortion and postpartum bleeding. With acute postpartum hemorrhage, the use of oxytocin (Wyeth-Ayerst Laboratories, Philadelphia, Pa.) is initially effective if lacerations have been excluded along with retained products of conception. Suction curettage has also been suggested. In patients with delayed postpartum hemorrhage, suction curettage was found to be effective in virtually every case as reported by King,[1] but when ineffective, hysterectomy was used. Alternative to hysterectomy is uterine artery ligation or angiographic embolization.

Packing of the lower uterine segment for control of postcesarean bleeding was reported by Druzin[2] to be effective, although packing has not been a favorite method to control postpartum bleeding. Delayed postabortion bleeding has not been addressed in the literature.

In these two cases, major surgery was contemplated but the interdiction of a dilute vasopressin solution paracervically slowed down the bleeding sufficiently to permit the insertion of a resectoscope, which was instrumental in determining the cause of bleeding and in stopping the bleeding. The benefits of the dilute vasopressin pack remain to be established but it has been found to be effective to control bleeding after resection of submucous myomas, which is the subject of a separate report. It is urged in institutions in which physicians are experienced in the use of the resectoscope that patients who have refractory bleeding after elective abortion and postpartum hemorrhage be managed with a dilute vasopressin injection followed by operative hysteroscopy. Perhaps similar patients can be managed as in these two cases thereby avoiding major operative procedures and even angiographic embolization, which in itself is not totally benign.

Computerized analysis of episodic changes in fetal heart rate variation in early labor

G.S. Dawes, DM, S.K. Rosevear, MD, L.C. Pello, MD, M. Moulden, and C.W.G. Redman, MD
Oxford, England

Fetal heart rate variation in early labor was measured by computerized analysis in cyclic episodes of low or high variation in 136 women at 37 to 42 weeks' gestation. The amplitude (mean ± SE) in episodes of low variation was 20.6 ± 0.4 milliseconds; in high variation it was 57.3 ± 1.1 milliseconds. The duration (mean ± SE) of low episodes (24.3 ± 1.3 minutes) was less than that of high episodes (45.1 ± 2.7 minutes) but was sometimes >1 hour. In episodes of low variation the amplitude was <5 beats/min long term in 11% and <2.5 milliseconds (pulse intervals) short term in 8%; these measures would be predictive of intrauterine death if persistent before birth. We conclude that the use of decreased fetal heart rate variation as a diagnostic sign of acute fetal hypoxemia in labor is incorrect, because changes of this size occur randomly as a consequence of fetal sleep states. There was no significant correlation between fetal heart rate variation over the last hour of labor and umbilical arterial base deficit on delivery. (AM J OBSTET GYNECOL 1991;165:618-24.)

Key words: Fetal heart rate, fetal behavior, computer analysis, sleep cycles, labor

Many reports show loss of baseline fetal heart rate (FHR) variation to be a reliable sign of impending death before birth.[1,2] From computerized analyses we reached the conclusion that reduced FHR variation was the single most reliable sign of hypoxemia,[3] developing acidemia, and imminent intrauterine death before the onset of labor. There are few direct measurements of FHR variation and its episodic change with fetal states (quiet or active) in early labor near term. It was anticipated that large changes in FHR variation with fetal state, or the presence of prolonged episodes of either state, or diurnal modulation of these phenomena might complicate the interpretation of subsequent changes in FHR pattern with the progress of labor. We therefore undertook a study principally in early labor, ≥2 hours before the onset of the second stage. We chose that phase of labor to avoid the confounding effect of large decelerations that attenuate the measured duration of episodes of low or high FHR variation. We also studied records of labor and delivery that were not complicated by the appearance of large decelerations.

Patients and methods

One hundred thirty-six patients were selected from a group of 500 who required continuous fetal monitoring in labor during the period 1986 through 1988. All patients had a gestational age of >37 weeks. Umbilical arterial blood gas values were available at delivery (measured at 37° C, ABL 3 Radiometer, Copenhagen), and FHR data were available from at least 3 hours before the onset of the second stage of labor. The initial

FHR analysis was restricted to the early first stage, ≥2 hours before the onset of the second stage. A subset of the data comprised recordings of 51 patients from ≥7 hours before the second stage of labor. On average, recording was begun 7.1 hours before delivery. Table I shows the obstetric characeristics of these patients and the reasons for FHR monitoring. Labor was induced in 95 patients (70%). Within the group 12 patients in whom there were no large decelerations (defined below) were studied throughout the first and second stages of labor.

The maternal age (mean ± SE) was 27.7 ± 0.47 years. No opiate analgesic was administered during the early first stage of labor. The incidence of epidural analgesia was 65% overall, higher in spontaneous labor (83%) than after induction (58%). The duration (mean ± SE) of the first stage was 8.6 ± 0.39 hours, and the second stage was 62.5 ± 5.8 minutes. The birth weight (mean ± SE) was 3.28 ± 0.045 kg (45.7 ± 2.6 percentile[4]), with Apgar scores of 7.5 ± 0.17 at 1 minute and 9.8 ± 0.06 at 5 minutes. At delivery the mean umbilical arterial pH was 7.22 ± 0.008, and the base deficit was 8.6 ± 0.36 mmol/L. Four infants were admitted to the special care baby unit, two because of birth asphyxia and one because of low birth weight. The reason for the fourth baby's admittance is unknown. The final outcome was satisfactory for all. There were no twins.

Management of labor		15

IUGR, Intrauterine growth retardation.

FHR analysis. The FHR was recorded (model 8040, Hewlett-Packard Co., Andover, Mass.). The monitors were interfaced to computers (Sage II, Sage Computer Technology, Reno), which sampled the RS 232 port 10 times per second. The FHR signal was recorded by scalp clip electrocardiography in 120 patients (88%), by ultrasonography in one patient, and by both methods, switching to electrocardiography as labor progressed, in the rest. The analysis was not allowed to influence clinical decisions. The pulse interval was validated by an error algorithm[5]; the mean valid intervals were averaged over a period of one sixteenth of a minute (3.75 seconds) and filed with the tocodynamometer measurement. Signal loss was calculated as the proportion of one-sixteenth–minute epochs during which no valid fetal pulse interval measurement was available. The records were of good quality; signal loss (mean ± SE) was 1.8% ± 0.23%.

A baseline was fitted to the FHR record,[6] modified to take account of the more variable basal heart rate encountered in labor, and updated hour by hour. The basal heart rate was measured during episodes of low FHR variation, where present; otherwise, it was calculated from the frequency distribution of pulse intervals to avoid bias through accelerations or decelerations. Accelerations were defined as ≥10 beats/min for 15 seconds' duration. Decelerations were defined as >10 beats/min for >60 seconds' duration or >20 beats/min for >30 seconds' duration. The area of decelerations, below the baseline, was calculated as the number of lost beats.[6]

Long-term FHR variation (band width 16 per minute to 1 per 10 minutes)[7] was calculated as the mean minute range of pulse intervals in milliseconds, excluding decelerations. The mean range of long-term FHR (pulse interval) variation was 45.9 ± 1.1 milliseconds. Episodes of low or high long-term FHR variation were identified as at least 5 of 6 consecutive minutes in which the range of pulse intervals was >32 milliseconds or <30 milliseconds, respectively (e.g., Fig. 1). Short-term FHR variation was calculated as the mean one-sixteenth–minute epoch-epoch variation, excluding decelerations.[7] Analysis was terminated in 6 of the 136 records when large decelerations (>20 lost beats) appeared.

The FHR data were plotted by using the format illustrated previously[6] to check the baseline fit, and also to provide a synoptic display of the variation and numbers of accelerations, decelerations, and uterine contractions every hour for each patient. All results were given as means ± SE unless otherwise stated. Statistical tests were either the Student *t* test or Wilcoxon's matched-pairs signed-rank test, as appropriate.

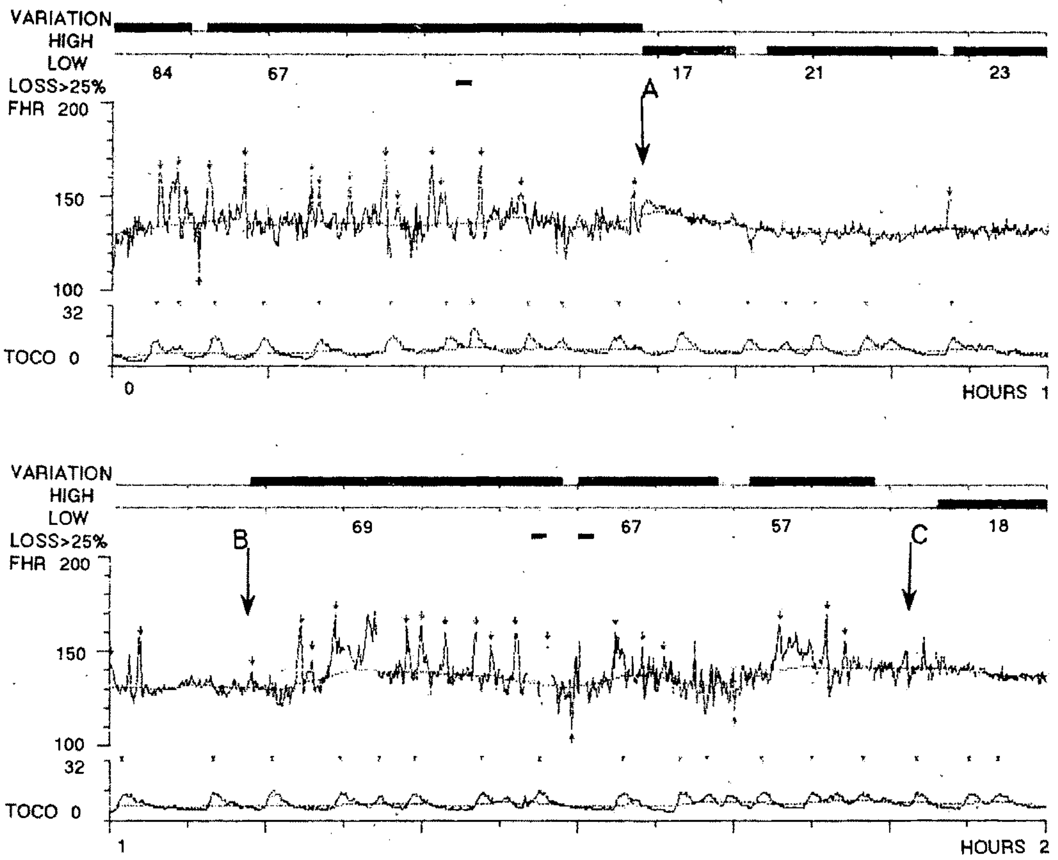

Fig. 1. Computer analysis of 2 hours in the early first stage of labor at 40 weeks' gestation shows successive episodes of low *(A-B)* and high *(B-C)* FHR variation. The mean range of long-term variation was 50 milliseconds, though episodes of low variation averaged 20.7 and high variation averaged 66 milliseconds. No analgesia was given; at delivery, umbilical arterial pH was 7.26 and base deficit was 7 mmol/L.

Results

In 73% of the records there were one or more episodes of both low and high FHR variation. In 23%, there was only one episode of high variation; this was not surprising because these episodes often exceed 1 hour in duration (see below). In 3%, there was only one episode of low variation.

Amplitude of FHR variation in high or low episodes. First, we examined the amplitude of long-term FHR variation in early labor (≥ 2 hours before the onset of the second stage), either spontaneous or induced. To obtain a fair sample, we selected patients whose fetuses were not acidemic at delivery, as judged by the umbilical arterial base deficit (<8 mmol/L), and for whom there were ≥ 2 hours of data available. Table II shows no significant difference in the mean amplitude of FHR variation, in episodes of high or low variation, between 37 patients in whom labor was induced and 18 in whom it occurred spontaneously. For comparison, Table II shows that even in 15 fetuses who had severe metabolic acidemia at delivery (umbilical artery base deficit: range, 13 to 26 mmol/L; mean, 16.4 mmol/L), FHR variation was the same as in the other two groups at this early stage of labor.

In 525 hours of data recorded for all 136 patients, there was no significant correlation between the FHR variation, recorded in episodes of high or low variation, and either gestational age (Fig. 2) or base deficit at delivery. The variation (mean ± SE) in low episodes was 20.6 ± 0.4 milliseconds (range 14.2 to 29.6 milliseconds); in high episodes it was 57.3 ± 1.1 milliseconds. Fig. 2 illustrates the large variation averaged per patient in early labor, from an extreme of 14.2 milliseconds (in low episodes) to 99.4 milliseconds (in high episodes).

In the 91 patient records in which both were available, the ratio (mean ± SE) of long-term FHR variation in episodes of low and high variation was calculated as 0.39 ± 0.008 with a range of 0.23 to 0.73. There was no correlation with base deficit at delivery. The ratio (low/high) was significantly ($p < 0.02$) related to the absolute value of FHR variation in episodes of low variation, but the correlation was low ($r = 0.26$). Hence, there was only a small tendency for those fetuses with

Table II. Comparison of the amplitude of FHR variation in episodes of high or low variation

	No. of patients	*Mean hours per patient*	*Amplitude of long-term FHR variation* (msec)*	
			High variation	*Low variation*
Induced labor (<8 mmol/L base deficit on delivery)	37	4.8	56.0 ± 2.2	20.7 ± 0.6
Spontaneous labor (<8 mmol/L base deficit on delivery)	18	6.1	58.4 ± 3.0	20.5 ± 0.6
Labor ending in severe acidemia (>12 mmol/L base deficit on delivery)	15	3.2	56.7 ± 2.2	21.5 ± 1.0

Blood samples were taken from umbilical artery at delivery.
*None of the mean differences are statistically significant.

lower FHR variation in low episodes to be lower in high episodes.

Measurements of long-term FHR variation (in terms of pulse frequency, beats per minute) in episodes of low FHR variation are normally distributed (Fig. 3). The incidence of measurements of low amplitude (<5 beats/min) was 11.1% of the total (n = 287).

Duration of episodes of high or low FHR variation. The duration (mean ± SE) of episodes of high FHR variation per hour was not significantly different in patients in spontaneous (19.9 ± 1.90 minutes) or induced (21.5 ± 1.14 minutes) labor. Nor was the duration (mean ± SE) of episodes of low FHR variation per hour different in spontaneous (14.5 ± 1.10 minutes) or induced (12.9 ± 0.67 minutes) labor. Because the frequency distributions were not normal, these calculations were repeated with a log transformation, which normalized the distribution and gave the same results, that is, no significant differences. The durations per hour of high or low episodes of FHR variation were not significantly related to outcome as judged by the arterial base deficit at delivery.

We concluded that it was safe to amalgamate the results from all fetuses. Episodes of low FHR variation were selected where bounded at either end by episodes of high variation and vice versa (see Fig. 1, A to B, B to C). Episodes of low variation may be interrupted transiently by a small brief deceleration or acceleration, and episodes of high variation by a brief deceleration; such transient interruptions were ignored for this purpose. There were 172 episodes of high variation in 85 patients, with a duration (mean ± SE) of 45.1 ± 2.7 minutes; there were 123 episodes of low variation in 62 patients, with a duration (mean ± SE) of 24.3 ± 1.3 minutes. Fig. 4 shows the frequency distribution by duration. Episodes of high variation are usually longer, but even episodes of low variation sometimes exceed 60 minutes in early labor. There were four episodes of low variation (3.25%) lasting more than 60 minutes in four different patients (2.9%).

Spencer and Johnson[8] reported the incidence of complete cycles of low and high FHR variation (indicative of quiet or active fetal behavior) to be less common in spontaneous labor (38%) than after induction (68%) at term. Our figures showed an equal incidence in spontaneous (72.5%) and induced (72.7%) labors, judged by the presence of at least one complete cycle of both low and high FHR variation.

Progress of labor and diurnal variation. To find whether the duration or amplitude of FHR variation (in high or low episodes) changed with time in early labor, we selected 51 patients for whom 5 to 12 hours of data were available. Thirty-three of the 51 patients had episodes of high variation, and 18 had episodes of low variation. The linear correlation of each variable (duration and amplitude of high and low variation) with time was calculated for each patient. In 7 of the 33 patients there was a significant ($p < 0.05$ to <0.001) fall in the duration of episodes of high variation with time. This fall was associated with an increase in the incidence of small decelerations. The slope (mean ± SE) (−1.05 min/hr) in the 33 patients overall also was significantly different from zero ($p < 0.05$). The size of the slope was not related to administration of epidural anesthesia or otherwise. None of the other variables (amplitude in episodes of high variation; duration or amplitude in episodes of low variation) were significantly related to time.

The data were also examined in relation to 24-hour clock time. Antenatal observations had shown a large rise in FHR variation in the early evening, from 6:00 PM to midnight, mainly as a result of the increased duration of episodes of high variation.[9] Records for six of the seven patients in whom the duration of episodes of high variation fell significantly in early labor spanned the time period in question. Over this period of time, the mean duration fell in 14 patients (−0.65 min/hr), but not statistically significantly.

Basal FHR and long-term FHR variation. There was an increase in basal FHR in association with episodes of high FHR variation, but the effect was small, a statistically significant ($p < 0.01$) increase of 2.0 ± 0.38

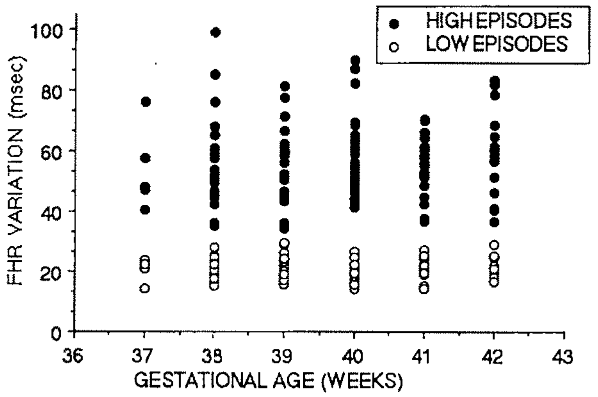

Fig. 2. Distribution of the mean values of long-term FHR variation in episodes of high (●) or low (○) FHR variation with gestational age.

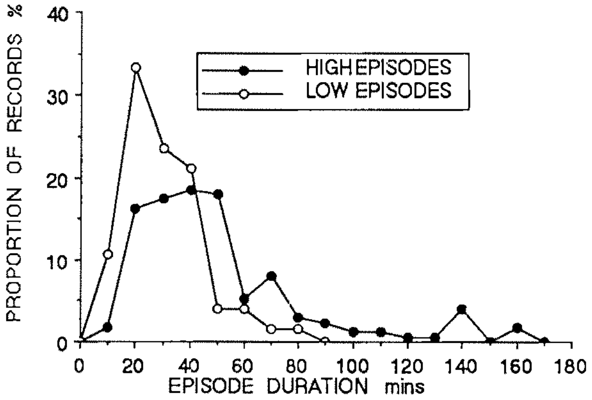

Fig. 4. Frequency distribution of the duration of episodes of high (●) or low (○) FHR variation, evidently skewed.

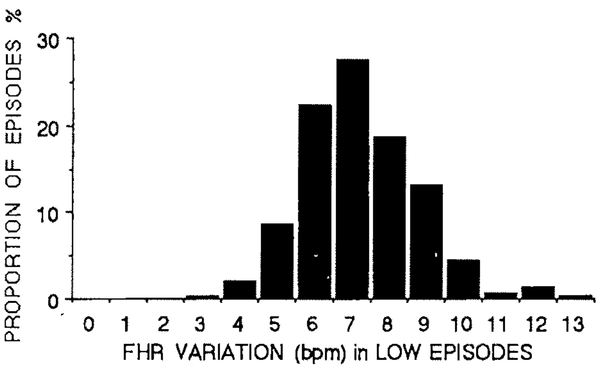

Fig. 3. Frequency distribution of long-term FHR variation (in terms of pulse frequency beats per minute) in episodes of low FHR variation. Eleven percent of these episodes had a mean value of <5 beats/min.

beats/min in episodes of high as compared with low variation, averaged from 51 patients (135 sets of measurements; high-low-high or vice versa). There was no relation between the size of the increase and the basal rate in low episodes.

At the start of recording, the mean basal FHR (mean ± SD) was 138 ± 8.0 beats/min; there was a small downward trend, statistically nonsignificant, with gestational age (37 to 42 weeks). During the course of the early first stage of labor (a period of 2 to 10 hours, before the onset of large decelerations or the last 2 hours before the second stage), FHR rose by 3.7 ± 11 beats/min. However the range of change was large, from −13 to +43 beats/min. The frequency distribution of changes was approximately normal. In 11 fetuses at 39 to 42 weeks' gestation, there was a rise in FHR by 20 to 43 beats/min to values of 154 to 180 beats/min; all were in mothers who had received epidural analgesia. Yet there were continued episodic changes in FHR variation; the arterial base deficit on delivery was relatively low (mean, 7.0 mmol/L, range 3 to 12 mmol/L).

Short- and long-term FHR variation. When long-term FHR variation is attenuated before birth (as in fetuses with intrauterine growth retardation and reduced end-diastolic umbilical blood flow velocity), both short- and long-term FHR variation must be measured.[7] Occasionally, there is a slow, sinusoidal rhythm of amplitude sufficient to constitute high variation superimposed on an otherwise flat trace, not uncommonly before death in utero. Measurement of short-term FHR variation is therefore a better guide to the identification of terminal traces (<2.5 millisecond short-term variation). The ratio (mean ± SD; short term/long term) in early labor was 0.20 ± 0.039, $r = 0.74$, consistent with antenatal observations. Ten of the 51 patients with records of greater length had episodes of short-term low FHR variation ≤2.5 milliseconds; in 5 patients, there were 5 to 7 such episodes lasting 5 to 28 minutes. Their presence was not related to a high base deficit on delivery (mean 7.5 mmol/L; range 5 to 12 mmol/L).

Patients with no large decelerations. Twelve patients had no large decelerations, so that measurements of episodes of low and high FHR variation could be made until delivery. Seven (58%) patients had received epidural analgesia (compared with 65% of the 136 patients). The mean duration of the first stage (8.3 ± 1 hour) was similar to that of the whole group; that of the second stage was a little longer (89 ± 16.7 minutes). In eight of the patients, episodes of low and high FHR variation continued until delivery; in the other four, long episodes of high FHR variation continued through the second stage of labor. Hence, there is a case for believing that fetal sleep states continue throughout labor, as suggested by Spencer and Johnson.[8]

FHR variation in the last hour of labor and base deficit at delivery. If episodic cycles of FHR variation persist in labor randomly with time, then we should expect that there would be no correlation between FHR variation and the fetal acid-base status at delivery. There were 125 (92%) patients in whom the last hour of labor was complete (<10% missing), with long-term FHR variation (mean ± SE) 48.3 ± 1.85 milliseconds (range 18 to 155 milliseconds) and mean arterial base deficit 8.7 ± 0.39 mmol/L (range 1 to 26 mmol/L). There was no significant correlation between the FHR variation averaged over the last hour of labor and the umbilical arterial base deficit at delivery ($r = 0.04$).

Comment

The most important conclusions from these observations are that (1) measured episodic FHR variation continues in labor; (2) the amplitude of FHR variation in episodes of low variation overlaps that predictive of abnormal antenatal fetal outcome; and (3) no significant correlation between long-term FHR variation and base deficit on delivery exists.

Before birth, very low FHR variation (short-term <2.5 milliseconds; long-term <12.5 milliseconds or <4.2 beats/min) maintained for 1 hour is diagnostic of impending death in fetuses who are growth retarded and chronically hypoxemic.[3] Fetuses with such gross and prolonged reduction of FHR variation are occasionally encountered in early labor, with an incidence of <1 in 500. In another category of fetus, FHR variation falls rapidly and abnormally in association with a terminal decline in basal rate in gross end-stage bradycardia. Excluding these two rare events, we must consider the circumstances in which FHR variation falls in labor to limits that may be predictively hazardous. Fetal rest-activity cycles were described >10 years ago[10] and persist in labor, but the implications for FHR analysis have not been faced. The concept of a smooth FHR trace preceding fetal death in utero derives from earlier studies associated with the introduction of "electronic evaluation of the fetal heart rate" by Hon[11] and others.[12-14] However, in some of these studies the patients had received diazepam, the effects of which on FHR were not appreciated at that time. In other studies, there were no records of whether mothers were given drugs, nor were there records of whether the duration of low FHR variation was of recent origin or might have preceded the onset of labor; it is impossible to be sure that the fetuses were not already compromised before labor.

It has been too readily assumed that acute fetal hypoxemia causes a prolonged reduction of FHR variation. The evidence is indirect and slight. In both sheep[5] and rhesus monkeys[15] acute hypoxemia causes an increase in FHR variation. For obvious reasons, no such direct experiments have been made in human beings. Growth-retarded and chronically hypoxemic human fetuses have reduced FHR variation before birth, yet when the PaO_2 is rapidly increased at delivery, FHR variation is not restored to normal levels at once.[16] There are alternative explanations of the reduced FHR variation in chronic hypoxemia associated with growth retardation that have not yet been tested; for example, the variation could be because of the reduced amino acid supply or altered fetal metabolism. The mechanism is unknown.

This study differs from that of Spencer and Johnson[8] in design and in some results. First, measurements were made with the aid of computers, not by visual analysis, and mostly during the early part of the first stage of labor. Our measurements were independent of observer variation, which has been found to be significant.[17] In Spencer and Johnson's identification of behavioral cycles, observer variability amounted to 11%. Second, we measured the amplitude of FHR variation. The results were similar in several respects. Thus we all concluded that there were well-defined episodes of low and high FHR variation in the first stage of labor similar to those observed before birth. Likewise, there was no evidence of diurnal variation.

The duration (mean ± SE) of episodes of low FHR variation was no different (24.3 ± 1.3 minutes) from Spencer and Johnson's[8] measurements (25 ± 0.4 minutes; SE calculated from their Table II). Although the duration of episodes of high variation (45.1 ± 2.7 minutes) in our study was less than in theirs (66 ± 2.5 minutes), the frequency distribution is skewed and the computer picks up brief, easily overlooked episodes. We found a decline in the duration of episodes of high FHR variation with time. Therefore our lower values cannot be attributed to selection of the earlier part of the first stage of labor; Spencer and Johnson included the entire first stage. Our results agree with the durations of fetal behavioral states (median values in 1F 17.5 minutes, in 2F 46 minutes), estimated by measuring fetal body, breathing, and eye movements and by observing FHR variation, before birth at 38 weeks' gestation.[18]

A more important difference is in the incidence of successive episodes of FHR cycling, which according to Spencer and Johnson[8] is less often present in spontaneous labor (38%) as compared with induced labor (68%), but only significantly different when the record length is shorter. Our results showed an identical incidence in spontaneous and induced labor. Our criteria were computer analysis and the presence of at least one completed cycle; Spencer and Johnson used visual analysis and required two cycles before recognizing the presence of cycling. Our patients had a higher incidence of epidural analgesia in spontaneous labor, but that would have been expected to reduce cyclic behavioral activity in the fetus, if it had any effect at all. Also, whereas Spencer and Johnson concluded that 48% of all cardiotocograms with evidence of behavioral cycling had periods when FHR variation was <5 beats/min, we found a lower incidence.

We conclude that episodic changes in FHR variation normally persist in labor, and we speculate that such changes may modify the pattern of decelerations. The allegation that an episode of low FHR variation always indicates danger needs reconsideration.

We thank many midwives and clinical colleagues for their help with the collection of data.

Ultrasonographic diagnosis of symptomatic deep venous thrombosis in pregnancy

Joseph F. Polak, MD, and Diane L. Wilkinson, MD
Boston, Massachusetts

Color flow imaging combined with compression ultrasonography were used to prospectively evaluate symptomatic patients first seen with suspected deep vein thrombosis during pregnancy. The incidence of symptomatic deep vein thrombosis (7 of 10,000 deliveries) shown prospectively by ultrasonography was similar to that of historic controls who had a diagnosis confirmed by venography (11 of 26,191 deliveries). A preferential pattern of proximal left-sided iliac or femoral vein involvement was common to both cohorts, being seen in five of the seven cases diagnosed by ultrasonography and eight of the eleven cases diagnosed by venography. We conclude that ultrasonography, consisting of compression ultrasonography and color flow imaging, can replace venography in the diagnosis and evaluation of the extent of symptomatic deep vein thrombosis during pregnancy. (Am J Obstet Gynecol 1991;165:625-9.)

Key words: Venous thrombosis, ultrasonography, pregnancy

Pregnancy is a well-recognized risk factor in the development of deep venous thrombosis in women younger than 40 years of age.[1] This diagnosis has until recently been made on clinical grounds,[1, 2] by venography,[3] or with the use of impedance plethysmography.[4-5]

Compression ultrasonography has been shown to have an accuracy >95% for the diagnosis of venous thrombi located within the femoral and popliteal venous segments.[6-9] Although it might be possible to infer that the same accuracy is attained in the pregnant patient, this issue has only been addressed in part in a report of three cases.[10]

This study proposes to evaluate the utility of color flow imaging and compression ultrasonography in the diagnosis and evaluation of the extent of symptomatic deep vein thrombosis in the antepartum patient.

Material and methods

Prospective cohort. Antepartum patients first seen with clinical suspected symptomatic lower extremity venous thrombosis were prospectively studied between March 1988 and March 1989. During this time interval, 10,000 deliveries were performed at our institution. There were 28 patients who ranged in age from 17 to 40 years (mean, 26.8 years ± 6.1 SD). When first seen, patients were on average 26.4 ± 9.5 weeks into their pregnancy for a range of 6 to 39 weeks. All complained of leg swelling, eight had additional complaints of calf pain, and eight localized the pain to the thigh.

Retrospective cohort. The medical records and venograms of all antepartum patients identified retrospectively as having had venography performed between August 1984 and April 1987 were reviewed according to institutional guidelines. Twenty-two such cases were identified. The number of deliveries during this time period was 26,191. The average age of this group was 24.4 years ± 7.0 SD (range, 18 to 41 years). When first seen, these patients were on average 25 ± 8.1 weeks into their pregnancy for a range of 8 to 38 weeks.

Nonpregnant cohort. Between October 1988 and March 1989, 51 nonpregnant patients had both ultrasonography and venography performed because of the clinical suspicion of deep vein thrombosis of the lower extremity. There were 23 males and 28 females with an average age of 54.8 years ± 16.8 SD (range, 18 to 89 years). Forty-three patients were referred because of symptoms, whereas eight were undergoing postoperative surveillance for the presence of deep vein thrombosis. There were 39 inpatients and 12 outpatients.

Techniques. Ultrasonography was performed with the aid of a 5 MHz linear array transducer (Acuson, Computed Sonography, Mountain View, Calif.). The imaging protocol consisted of using distention of the common femoral vein in response to the Valsalva maneuver to exclude obstructing thrombus in the iliac veins.[11] The remainder of the femoral popliteal venous system was then surveyed with color Doppler flow imaging with flow augmentation in the femoral and popliteal vein to exclude nonobstructing thrombosis. Compression ultrasonography was also performed

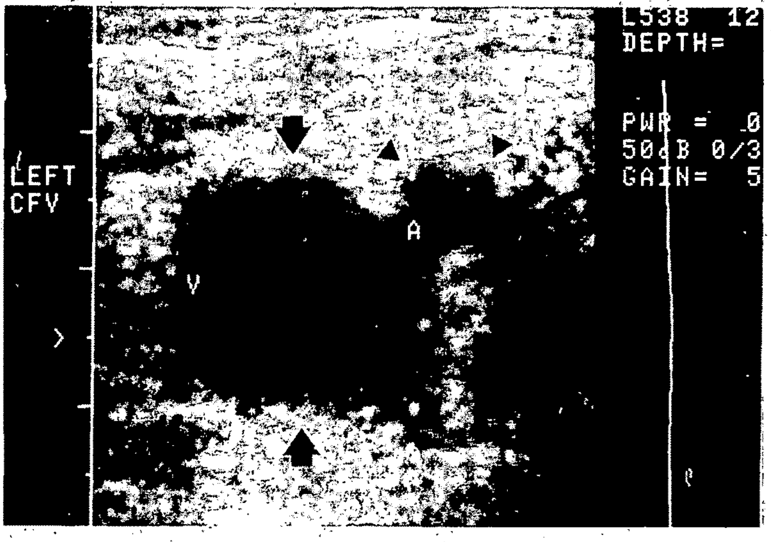

Fig. 1A. This transverse view of the left common femoral vein shows a distended vein *(arrows)* medial to the artery *(arrowheads)*.

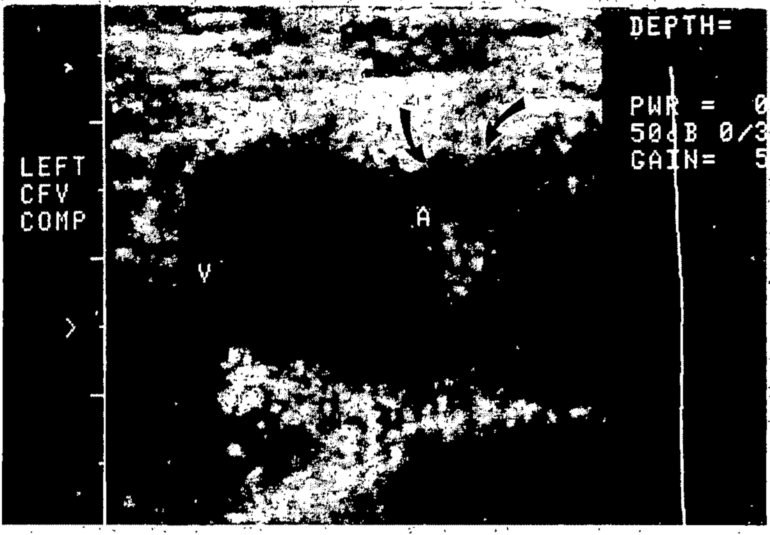

Fig. 1B. Progressive compression causes deformation of the artery *(curved arrow)* before the vein. This loss of compressibility in spite of the lack of echogenic signals within the vein is diagnostic of venous thrombosis.

along the course of the femoral and popliteal veins with the transducer held transverse to the vein. All patients were examined in the supine position. The popliteal vein was imaged with the extremity in slight external rotation or froglike position. Deep vein thrombosis was diagnosed when a venous segment was noncompressible and did not show any flow signals. If the patient manifested localized symptoms a survey was also performed at the site of symptoms, whether it be in the calf or in the thigh.[12]

Venography. Venography was performed with a modification of the approach described by Rabinov and Paulin[13] with a 23 or 25 gauge needle used to cannulate a dorsal pedal vein and dilute contrast material injected under fluoroscopic guidance.

Data analysis. Comparison of the distribution of venous thrombi was made using χ^2 statistics. Proximal venous thrombosis refers to either iliac, common femoral, or superficial femoral vein involvement with sparing of the popliteal veins. Distal venous thrombosis is limited to the calf and popliteal veins with sparing of either the iliac, common femoral, or superficial femoral veins.

Sensitivity and specificity were determined according to recommendations made by McNeil et al.[14] The sensitivity and specificity of the ultrasonographic imaging

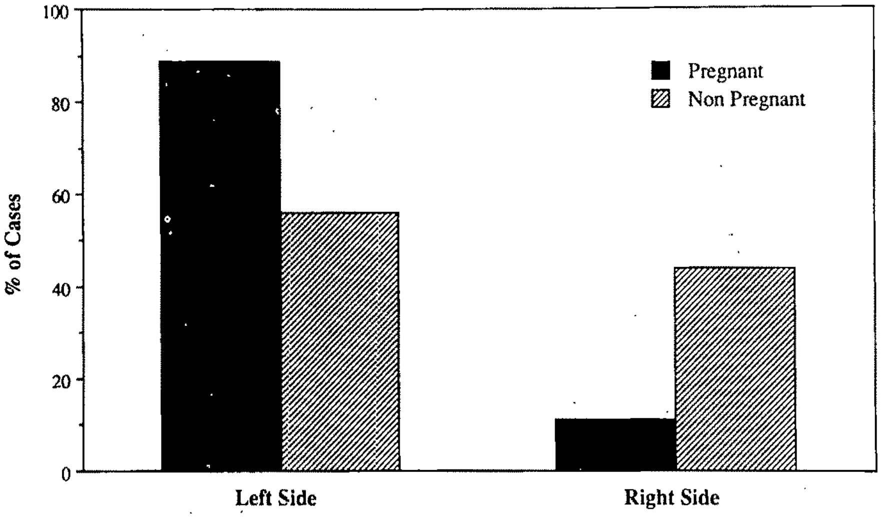

Fig. 2. The figure depicts the affected side of venous thrombosis in the patients studied. Comparison of the side involved by deep vein thrombosis in pregnant and nonpregnant patients shows the preferential left-sided involvement during pregnancy.

protocol was evaluated by comparison to the phlebographic results in the nonpregnant patients because none of the pregnant patients with ultrasonographic examinations underwent additional phlebography.

Results

Pregnant subjects. In the retrospective cohort, there were 22 patients in whom venography was performed out of 26,191 pregnancies at risk. In 11 of these, the diagnosis of deep venous thrombosis was confirmed. Thrombosis of the lower popliteal veins was noted in three, whereas proximal thrombus sparing the popliteal vein but involving the iliofemoral system was noted in the other eight. The left side was involved in all 11 cases. Venous thrombosis occurred during the first ($n = 2$), second ($n = 5$), and third ($n = 4$) trimesters.

In the prospective cohort diagnosed by ultrasonography, 28 subjects were suspected of having deep venous thrombosis. The diagnosis was made in seven instances by noting loss of compressibility and the absence of flow within the involved segment. Proximal venous thrombosis involving the iliac and femoral vein but sparing the popliteal vein was diagnosed in five of these (Figs. 1A and 1B). The left side was involved in five of the seven cases. Deep vein thrombosis occurred during the first ($n = 2$), second ($n = 1$), and third ($n = 4$) trimesters. All patients diagnosed by ultrasonography or venography were treated with heparin and went on to be delivered of infants. No cases of clinically evident pulmonary emboli were reported.

Nonpregnant subjects. A total of 45 of 51 venograms were judged to be diagnostic with three being technically limited and three nondiagnostic.

There were 13 instances of negative venograms; all 13 had a normal noninvasive ultrasonographic examination. Three of seven cases of below-knee thrombosis were prospectively detected. The 25 instances of femoropopliteal venous thrombosis were diagnosed prospectively by ultrasonography. There was a slight preferential left lower extremity involvement (14/25). Distal thrombosis involving the popliteal and femoral veins but sparing the iliac veins was seen in 22 of 25 cases. Proximal thrombosis limited to the iliofemoral veins with sparing of the popliteal veins was seen in three patients with pelvic malignancies.

Pregnant vs nonpregnant subjects. Preferential left-sided involvement (Fig. 2) was more common in the pregnant population (16/18 vs 18/32; $\chi^2 = 4.24$; $p < 0.05$). Proximal iliofemoral thrombosis was more common in the pregnant population (Fig. 3) as compared with the nonpregnant population (13/18 vs 3/32; $\chi^2 = 18.1$; $p < 0.001$).

Comment

This study confirms that the incidence of symptomatic deep venous thrombosis during pregnancy is low and similar to that cited in previous reports (i.e., between 0.4 to 0.7/1000 deliveries).[3, 4] Among subjects younger than 40 years of age, pregnancy is a major risk factor for venous thrombosis and pulmonary embolism.[1] Once recognized, venous thrombosis is treated with judicious anticoagulation.[15, 16] The use of heparin is favored, in spite of the logistical difficulties of its administration, because of the possible teratogenic effects of sodium warfarin (Coumadin).

A previous report of three cases suggested that venous ultrasonography could be used to make the diagnosis of deep vein thrombosis during pregnancy.[10]

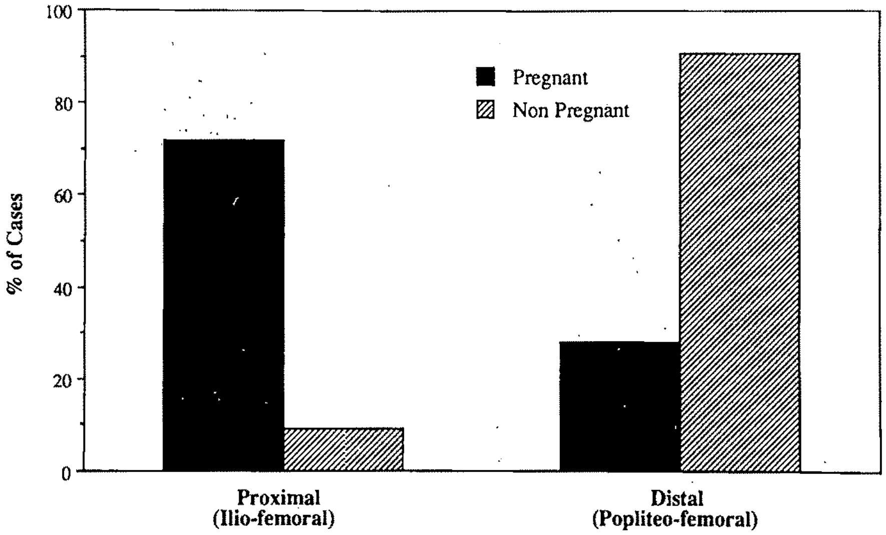

Fig. 3. This figure shows the distribution of venous thrombosis in the leg veins. Proximal iliofemoral involvement with popliteal vein sparing is more likely during pregnancy.

This study examines the utility of ultrasonography in a larger number of patients. A side-by-side comparison with venography was difficult to justify because of the risks of contrast material and radiographs to both mother and fetus. The latter is important inasmuch as the fetus is exposed to radiation from radiographs taken of the upper thigh and pelvis. However, these films are important because this and previous studies have shown preferential iliac vein involvement with downward spread of thrombosis during pregnancy. We therefore studied the diagnostic utility of ultrasonography in two ways. The first was to confirm that during pregnancy the pattern of deep venous thrombosis seen prospectively with ultrasonography is similar to that seen when venography is performed. The historic population was made up of all pregnant patients suspected of having symptomatic deep venous thrombosis from among 26,191 consecutive pregnancies. The clinical suspicion of venous thrombosis led to venography. The prevalence of deep venous thrombosis in this group was 50%. This high proportion of positive venograms suggests a clinical hesitation in performing phlebography during pregnancy. In this prospective cohort, venous ultrasonography showed a similar distribution of venous thrombus. The number of ultrasonographic examinations performed in this group (28/10,000) is higher than that for the patients who had venography (22/26,191) and suggests that the diagnostic threshold for performing the test is lower. This possibility is supported by the lower proportion of positive examinations (25%) in the group diagnosed by ultrasonography. Both groups did, however, show a similar preferential left-sided involvement of venous thrombosis. The pathophysiologic mechanism responsible for this phenomenon is believed to be increased stasis because of the crossing of the iliac vein beneath either a low bifurcating aorta or the right iliac artery.[17] Besides a simple compressive effect, there is also a higher incidence of venous webs forming at this site.[14]

Color Doppler ultrasonography and compression ultrasonography were compared with venography in nonpregnant patients not only to verify the overall accuracy of the technique but also to establish the pattern of involvement in the nonpregnant population. Although preferential involvement of the iliac and proximal femoral veins is common in the pregnant patient, it is uncommon in the nonpregnant group.[19, 20]

In a recent retrospective review, Becker et al.[21] show the sensitivity and specificity of ultrasonography for femoropopliteal system thrombosis to be 96% and 99%, respectively. When calf thrombi are included, the diagnostic sensitivity of the test decreases. This finding may not apply to future studies that will focus on visualization of the paired perineotibial and muscular veins of the calf.[12] The use of anticoagulation for calf vein thrombosis, already controversial in the nonpregnant patient, is in fact harder to justify during pregnancy.

The addition of color Doppler imaging to compression ultrasonography is considered to be supportive in nature. In none of these instances was the diagnosis of deep venous thrombosis made without loss of compressibility being present. In fact poor venous flow was often seen during the third trimester with the patient supine and resolved in the opposite decubitus position in all cases. Color Doppler ultrasonography by itself could have led to false-positive diagnoses.

We therefore conclude that color Doppler ultrasonography and compression ultrasonography can be used to make the diagnosis of deep venous thrombosis of the lower extremity during pregnancy and to effectively replace venography.

Treatment of fetal supraventricular tachycardia with flecainide acetate after digoxin failure

Alexander D. Kofinas, MD, Nicolas V. Simon, MD, Henry Sagel, DO, Ellen Lyttle, RN, Nancy Smith, RN, and Karen King, RDMS

York, Pennsylvania

Transplacentally administered digoxin is the drug of choice for the treatment of fetal supraventicular tachycardia. We describe a case of fetal supraventricular tachycardia associated with fetal hydrops that did not respond to digoxin treatment because of a lack of transplacental passage. In contrast, flecainide acetate crossed the placenta and cured the fetus. The clinical implications of this new treatment are discussed. (Am J Obstet Gynecol 1991;165:630-1.)

Key words: Flecainide acetate, digoxin, fetal tachycardia

The treatment of fetal supraventricular tachycardia has been a difficult task. The most commonly used drug is digoxin alone or in combination with propranolol or verapamil. We describe a case of supraventricular tachycardia unresponsive to digoxin that was successfully treated with flecainide acetate.

Case report

A 22-year-old, gravida 1, para 0 woman was referred to the York Hospital antenatal testing unit at 31 weeks' gestation for fetal arrhythmia. Real-time ultrasound (Toshiba 270 a-sonolayer, Toshiba America Medical Systems, Tustin, Calif.) revealed mild hydramnios and fetal ascites. Fetal M-mode echocardiography revealed fetal supraventricular tachycardia at a rate of 240 beats/min with no evidence of atrioventricular block. Two-dimensional echocardiography revealed a structurally normal fetal heart with moderate dilatation. Duplex pulsed-wave and color Doppler ultrasonography revealed tricuspid regurgitation and reverse flow in the inferior vena cava. Myocardial contractility was decreased with a right ventricular fractional shortening consistently <20%. Treatment was initiated with digoxin transplacentally and 48 hours later the fetal heart rate (FHR) was 204 beats/min in spite of a maternal serum level of 2.1 ng/ml. Fetal umbilical vein level was 0.9 ng/ml (therapeutic, 0.9 to 2.0 ng/ml). Flecainide acetate was started at a dosage of 100 mg orally every 8 hours. Over the next 96 hours FHR converted to normal sinus rhythm of 120 beats/min. Maternal flecainide trough levels drawn at 24 hours, 48 hours, and 96 hours after initiation of treatment were 0.5, 0.6, and 0.8 μg/ml (therapeutic level, 0.2 to 1 μg/ml). No maternal side effects were noted and daily maternal electrocardiogram for 3 days was normal. At 56 hours after conversion a decision was made to discontinue both the digoxin and flecainide because of nonreactive nonstress test (NST) results, which gradually became reactive after discontinuation of flecainide.

Approximately 36 hours after discontinuation of treatment the FHR returned to pretreatment levels. Flecainide acetate 150 mg was given orally alone and 30 minutes later the FHR converted to normal. The patient received an additional 150 mg in 12 hours and every 12 hours thereafter. After 4 days at a stable heart rate of 120 beats/min with nonreactive NST results, flecainide was gradually decreased by 50 mg decrements to 50 mg every 12 hours, and over this period of time the NST results became reactive with normal beat-to-beat variability. Maternal serum flecainide trough level during this period was 0.2 μg/ml.

Right ventricular function improved, inferior vena cava flow pattern returned to normal, and cardiac dimensions became normal within the first 20 days. The placental thickness declined from 6.4 to 4.2 cm and fetal ascites resolved completely in 10 days.

The patient was delivered vaginally at 41 weeks' gestation. Maternal and fetal serum trough levels of flecainide at the time of delivery were 0.2 and 0.1 μg/ml, respectively. The Apgar scores were 9 and 10 at 1 and 5 minutes, respectively, and the venous blood gas values were normal. Birth weight was 3480 gm. Postnatal echocardiography was normal. At 48 hours after birth the neonate was started on prophylactic digoxin.

Comment

Digoxin has been the drug of choice and its safety is recognized. However, digoxin alone is not successful in all cases and this most likely is a result of poor transplacental passage.[1] Flecainide has been used successfully in the treatment of children with tachyarrhythmia resistant to conventional treatment and was found to

be safe.[2] Flecainide treatment of fetal supraventricular tachycardia by intravenous administration to the mother resulted in conversion of the fetal arrhythmia to regular sinus rhythm in less than 10 minutes.[3] In this case, toxic maternal serum levels of digoxin (2.1 ng/ml) resulted in a fetal serum level of 0.9 ng/ml, which is at the lowest end of the therapeutic range. The addition of propranolol was rejected because of the theoretic risk of intrauterine growth retardation and the addition of verapamil was rejected because of its association with fetal and neonatal deaths. Direct intramuscular fetal injections were considered unsafe in this patient. Flecainide acetate was then chosen because it has been shown to pass across the placenta rather easily with fetal levels as high as 86% of maternal serum levels.

Flecainide acetate in this case has been associated with nonreactive NST results and poor beat-to-beat variability, a dosage-related event that subsides spontaneously with the lowering of the dosage. Surveillance for fetal well-being was performed by means of biophysical profile when the beat-to-beat variability was poor and with twice-weekly NSTs when the beat-to-beat variability returned to normal. Fetal blood sampling for determination of digoxin level was instrumental in defining the reason for the failure of digoxin to control the tachycardia. We conclude that the use of flecainide acetate for the treatment of supraventricular tachycardia may be a safe and successful alternative for arrhythmias resistant to digoxin.

Antimicrobial therapy in preterm premature rupture of membranes: Results of a prospective, double-blind, placebo-controlled trial of erythromycin

James A. McGregor, MD, CM, Janice I. French, CNM, MS, and Kyung Seo, MD, PhD
Denver, Colorado

This study was conducted to evaluate the effectiveness of oral erythromycin treatment in safely prolonging pregnancy among women experiencing preterm premature rupture of membranes. Sixty-five women were randomly assigned to receive double-blind treatment with either erythromycin base or an identical-appearing placebo three times daily for 7 days. Only women between 23 and 34 completed weeks' gestation who did not have an indication for delivery were enrolled in the study. Pretreatment microbiologic tests were obtained and women were followed expectantly. Fifty-five women and their newborns completed the protocol and were fully evaluated. Overall, time from rupture of membranes to onset of labor and to delivery was longer, although not significantly, for erythromycin-treated women. Similarly, there was a trend for reduced neonatal intensive care (level II, $p = 0.07$). When gestational age at enrollment was controlled, erythromycin treatment of women between 28 to 32 weeks' gestation was associated with a prolonged interval from enrollment to delivery [erythromycin: 292 hours (5 to 679); placebo: 54 (12 to 323); $p < 0.044$]. Fifty percent of erythromycin-treated women between 28 to 32 weeks' gestation continued their pregnancies at least 13 days after premature rupture of membranes, whereas 50% of placebo-treated women were delivered of infants within 4 days ($p = 0.02$). Erythromycin treatment among women <28 and between 33 to 34 weeks' gestation was not associated with prolonged latency or other changes. There were no differences between erythromycin- and placebo-treated women in the occurrence of clinically recognized chorioamnionitis, postpartum endometritis, or neonatal infectious morbidity. In this double-blind, placebo-controlled trial, erythromycin treatment was well tolerated, safe, and associated with prolongation of pregnancy and reduced intensive neonatal care requirements for selected mother-newborn pairs with preterm premature rupture of membranes. (AM J OBSTET GYNECOL 1991;165:632-40.)

Key words: Premature rupture of membranes, treatment, antibiotic

Rupture of fetal membranes before the onset of labor and before completion of 37 weeks' gestation occurs among 1% to 2% of pregnancies and is directly related to 30% to 40% of preterm births.[1, 2] Optimal management of patients with preterm premature rupture of membranes (PROM) has not been defined, but requires balancing risks of prematurity versus those of maternal and perinatal infection.[3] Benefits of improved care for women with preterm PROM may be substantial. Goldenberg[4] calculates that an infant's chance of surviving without major handicap increases up to 3% each day between 23 and 30 weeks' gestation, regardless of membrane status.

Although the pathogenesis of preterm amniorrhexis remains incompletely understood, considerable information indicates that infection and inflammation within the amniochorion or the adjacent decidua likely precede some instances of preterm PROM.[5-8] Alternatively, ascending intrauterine infection after preterm PROM is a recognized cause of maternal and perinatal infectious morbidity. If infection is indeed a cause or contributing factor in preterm PROM as well as a complication that develops after rupture of membranes and hastens the eventual onset of labor, it is possible that appropriate antimicrobial therapy may benefit some women and their infants.[3, 9-13]

Therefore a prospective, randomized, double-blind, placebo-controlled study was undertaken to evaluate the efficacy of a short course of oral erythromycin to safely prolong gestation, reduce risks of maternal and perinatal infectious morbidity, and further define clinical and microbiologic circumstances in which erythromycin treatment may be beneficial after preterm PROM.

Methods

Between July 1986 and June 1988, 154 women were admitted to University Hospital, Denver, with rupture of membranes before 35 weeks' gestation. Rupture of

membranes was clinically documented by the presence of vaginal pooling of amniotic fluid or visualization of amniotic fluid released from the cervical os as well as observation of a ferning pattern on microscopic examination of a dried smear obtained from the vaginal pool or detection of alkaline pH with Nitrazine paper (E. R. Squibb and Sons, New Brunswick, N.J.). Women with singleton pregnancies and clinically documented rupture of membranes between 23 and 34 completed weeks' gestation were evaluated for study enrollment. Exclusion criteria included possible labor (demonstrated two or more regular uterine contractions every 10 minutes persisting after observation and intravenous hydration), presence of a maternal or fetal indication to facilitate labor or delivery (including evidence of chorioamnionitis, fetal distress, prolapsed cord, pregnancy-induced hypertension, abruptio placentae), placenta previa, cervical cerclage, known infectious process requiring antimicrobial therapy, use of vaginal or systemic antimicrobial agents in the preceding 2 weeks, presence of known uterine or fetal anomalies, history of vaginal bleeding within the prior month, serious maternal medical complications (such as diabetes mellitus, severe cardiac, kidney, liver, respiratory, or immunologic disease), or history of allergy or intolerance to erythromycin. Eighty-four women met study inclusion criteria, and 65 (66%) of the eligible women were successfully enrolled in the study protocol. Each participant signed written informed consent approved by the University of Colorado Health Sciences Center Human Subjects Committee. Informed consent could not be obtained from 19 women.

Ten women were subsequently excluded from analysis before breaking the treatment code. In four of these women, rupture of membranes was excluded by amniocentesis with injection of indigo carmine dye; all these women were delivered of infants at term. Two women with minimal or no prenatal care and poor dating criteria were excluded inasmuch as they entered labor and were delivered of term infants after one or two doses of study treatment. Labor was induced for one patient when pregnancy-induced hypertension was noted 1 day after enrollment. This infant was subsequently found to have trisomy 18 and died. One patient with rupture of membranes at 23 weeks' gestation was lost to follow-up after she left the hospital to return to her home state against medical advice. One patient, enrolled at 26 weeks' gestation with suspected membrane rupture since 18 weeks' gestation, was delivered of an infant with hypoplastic lungs and limb contractures who died within 48 hours of birth. Examination of the placenta revealed a partial molar pregnancy. The final patient was excluded because of a pharmacy error. The total analyzed sample included 55 women and their newborns.

Clinical evaluation. On enrollment, women were interviewed to obtain demographic, social, behavioral, medical, and obstetric information. During the initial sterile speculum examination, which documented rupture of membranes, microbiologic samples were obtained as follows. The anterior vaginal fornix and lateral vaginal wall, away from the cervix, were swabbed with sterile cotton-tipped swabs. One of these samples was rolled onto a slide and allowed to air-dry for Gram's stain evaluation for bacterial vaginosis and *Mobiluncus* species morphotypes with previously described criteria.[14] Material on a second swab was combined with a drop of 10% potassium hydroxide on a slide to test for release of amine odor (whiff test) and examined microscopically for yeast pseudohyphae. Another swab was combined with a drop of saline solution and examined microscopically for motile trichomonads.

Microbiologic methods. Cervicovaginal swabs were inoculated at the bedside onto 5% sheep blood agar (tryptic soy base, Remel, Denver) for recovery of group A and group B streptococcus, *Staphylococcus aureus*, *Gardnerella vaginalis*, and yeast spp. Additional vaginal swabs were inoculated into a standard mycoplasma transport medium for recovery of *Mycoplasma hominis* and *Ureaplasma urealyticum*. Separate endocervical swabs were immediately inoculated onto a chocolate agar and a modified Thayer-Martin medium split plate for recovery of *Neisseria gonorrhoeae*, and into sucrose-phosphate glutamate transport media for recovery of *Chlamydia trachomatis*.

Microorganisms were identified with standard techniques.[15] Cultures for *M. hominis*, *U. urealyticum*, and *C. trachomatis* were frozen at − 70° C and processed in batches. The presence of chlamydia was determined by combined technique. After 48 hours incubation at 35° C, inoculated cycloheximide-treated McCoy cell monolayers were treated with fluorescein-conjugated antichlamydial monoclonal antibody (Syva Microtrak, Syva Co., Palo Alto, Calif.) and examined microscopically for the presence of inclusions.[16] Negative cultures were not processed further. For recovery of *M. hominis* and *U. urealyticum*, a modified commercially available agar (Mycotrim GU, Hana Biologics, Inc., Alameda, Calif.) was inoculated with 1 ml of thawed transport media and processed according to established techniques. Posttreatment cultures were not obtained.

Study treatment. Study patients were randomly assigned to receive either erythromycin base 333 mg (E-Mycin, Upjohn Co., Kalamazoo, Mich.) orally three times daily or an identical-appearing placebo. Erythromycin and placebo tablets were double-blinded and distributed in sequentially numbered, identical bottles provided by The Upjohn Company, Kalamazoo, Mich. Study treatment continued until the patient entered active labor or for a total of 7 days. Treatment was randomized according to a computer-generated random number list. A copy of the randomization code was sealed by The Upjohn Company and kept in the University Hospital pharmacy for the duration of the study.

Women were hospitalized and managed expectantly with bed rest and bathroom privileges while being observed for evidence of continued fetal well-being, infection, or the onset of labor. Patients were examined twice daily for evidence of uterine tenderness and the presence, as well as odor and color, of amniotic fluid. Maternal temperature and pulse and fetal heart rate were determined every 4 hours until onset of labor. An external fetal monitor tracing was obtained daily to evaluate fetal heart rate parameters and to detect uterine contractions. Maternal white blood cell counts were performed every other day. Corticosteroids were not administered, and only two women received single doses of subcutaneous terbutaline before transport. Women found to be vaginally colonized with group B streptococcus were given appropriate antibiotic treatment, usually intravenous ampicillin in labor. Women with positive endocervical cultures for *C. trachomatis* were given appropriate antimicrobial treatment after delivery. Neonatal care providers were notified at delivery or as soon as results were available when either group B streptococcus or *C. trachomatis* were recovered from the mothers. Women with findings of urinary tract infection or significant bacteriuria were treated with a course of oral nitrofurodantoin. Follow-up information was obtained by review of maternal and newborn medical records 6 and 12 weeks after delivery, respectively.

Definitions. Gestational age was determined before data analysis and was based on overall best obstetric criteria that included last menstrual period, antenatal record of fetal growth, detection of fetal heart rate with fetoscope, ultrasonographic measurements, and neonatal gestational age assessment.[17] The latent period was defined as time from rupture of membranes to delivery. The diagnosis of chorioamnionitis was determined on the basis of clinical criteria of maternal fever or at least two of the following: tachycardia, uterine tenderness, foul amniotic fluid, fetal tachycardia, with or without maternal leukocytosis.

Data analysis. Sample size calculation performed before the study determined that a sample with 30 patients in each arm provided a 70% chance of detecting a 30% increase in the number of patients who continued their pregnancies for at least 1 week, with α set at 0.05. Data were summarized with descriptive statistics. Group differences for noncontinuous data were tested for significance with χ^2 or Fischer's exact tests (two-tailed). Continuous data were analyzed with the Student *t* test. Group differences for the time interval between rupture of membranes and entry into study and delivery were compared with survival analysis (SAS Lifetest procedure) log rank test or Wilcoxon rank sum test. A p value <0.05 was considered significant.

Results

Twenty-eight women were randomized to receive erythromycin and 27 received placebo. Demographic, historic, obstetric, and behavioral characteristics were similar between treatment groups (Table I). Ten (18.2%) of the enrolled women had completed <28 weeks' gestation; 24 (43.6%) were between 28 and 32 weeks' gestation, and 21 (38.2%) were >32 weeks' gestation at enrollment. Equivalent numbers of women in each treatment group received digital examination to assess cervical dilatation after rupture of membranes and before onset of the study. Multiple other demographic and historic factors (not presented) did not differ among study patients.

Risk factors associated with prematurity. Group differences for patients who received erythromycin or placebo for maternal and antenatal risk factors associated with prematurity are also shown in Table I. Five (17.9%) patients in the erythromycin group reported recreational drug use: one woman reported using intravenous heroin occasionally during early pregnancy; the remaining four patients in the erythromycin group and two (7.4%) patients in the placebo group reported occasional marijuana use. No patient reported using any form of cocaine.

Maternal medical problems were clinically well controlled and included first-trimester cholecystectomy and appendectomy (one patient), hypertension (two patients), depression (one patient), late second-trimester bronchitis and pneumonia (three patients), gestational diabetes (one patient), cholestatic jaundice (one patient), uterine myoma (one patient), and asthma (one patient). One patient in the placebo group was treated for pyelonephritis at 17 weeks' gestation; she was enrolled in the study at 32 weeks' gestation. Subsequent to entering the study, four patients (three erythromycin group, one placebo group) were treated with oral nitrofurodantoin for bacteriuria. Congenital anomalies were detected among three infants whose mothers had received erythromycin (two vessel cord; tracheal esophageal fistula with esophageal atresia, and ventral septal defect; metatarsus adductus) and two infants from the placebo group (two vessel cord and mild hydrocephalus).

Microbiologic findings. Microorganisms recovered at study initiation are listed in Table II. Similar types and numbers of isolates were recovered from each treatment group. *N. gonorrhoeae* was recovered from one erythromycin-treated patient at 28 weeks' gestation; this patient experienced an intrauterine fetal death within 12 hours of hospital admission and within

2 hours of a reassuring fetal monitor tracing. At delivery, a tight nuchal cord and foul odor of amniotic fluid were noted; placental pathology showed acute chorioamnionitis. Autopsy was refused.

Two (7.1%) patients in the erythromycin group and three patients (11.1%) in the placebo group had group B streptococcus recovered. One woman in each treatment group labored and delivered infants within 1 day of study enrollment and before return of culture results. Each of the other women with group B streptococcus received suitable intravenous antibiotic treatment, one patient in the erythromycin group received cephalexin and two women in the placebo group received ampicillin before labor and delivery. Each patient was retained in their original group. No instance of group B streptococcal neonatal sepsis occurred.

Women from whom *C. trachomatis*, *S. aureus*, or group B streptococcus were recovered were more likely to be >32 weeks gestation at study enrollment when compared with women without these microorganisms (p = 0.02, relative risk [RR], 3.6, 95% confidence interval [CI], 1.4 to 9.6). Conversely, bacterial vaginosis was identified frequently among women ≤32 weeks' gestation at study enrollment. Although not statistically different, nine (32.1%) women enrolled ≤32 weeks' gestation were identified as having bacterial vaginosis compared with 3 (16.7%) women who were >32 weeks' gestation at enrollment (p = 0.3). Similarly, women

from whom *U. urealyticum* was recovered were more often enrolled at lower gestational ages (87.5% of women ≤ 32 weeks' were positive for *U. urealyticum* versus 70.0% of women >32 weeks' gestation, $p = 0.2$). These women delivered infants weighing nearly 300 gm less (*U. urealyticum*–positive 1641.4 ± 461.0 gm versus *U. urealyticum*–negative 1937.0 ± 426.3 gm, $p = 0.07$).

Pregnancy outcomes. Table III and Figs. 1 and 2 show selected pregnancy outcomes. All patients delivered infants before 37 weeks' gestation. Overall, time from study entry to delivery was longer, although not significantly, for erythromycin-treated women (Table III). With the use of univariate analysis, these differences were significant for women who continued their pregnancies for at least 10 days (erythromycin: 13/27, 48.2%; placebo: 5/27, 18.5%; $p = 0.04$, RR 2.6, 95% CI 1.1 to 5.9). Survival analysis confirmed these findings (Fig. 1).

In spite of random assignment, women who received erythromycin tended to enter the study at a lower mean gestational age ($p = 0.08$). Because of these findings, data were stratified to control for gestational age at enrollment. Stratification (<28 weeks' gestation, 28 to 32 weeks, and ≥ 33 weeks' gestation) was performed to conform with clinical parameters that are associated with different perinatal outcomes among patients with PROM in our center. Among subjects enrolled <28 weeks' gestation, erythromycin-treated patients ($n = 6$) continued their pregnancies for less time than placebo-treated ($n = 4$) women (erythromycin: median 218, range [12 to 511] hours from study entry to delivery; placebo: median 582, range [127 to 734] hours).

Among women with PROM between 28 to 32 weeks' gestation, mean gestational ages at enrollment were similar (erythromycin: 30.3 ± 1.4 weeks versus placebo: 30.6 ± 1.4 weeks, $p = 0.6$). Erythromycin-treated women ($n = 15$) continued their pregnancies significantly longer (median 291, range [5 to 679] hours from study entry to delivery) than placebo-treated ($n = 9$) women (median 54, range [12 to 323] hours; $p = 0.044$). Survival analysis for this subgroup (28 to 32 weeks' gestation) of women showed that 50% of erythromycin-treated women continued their pregnancies from rupture of membranes at least 13 days, whereas 50% of placebo-treated women delivered infants within 3.8 days (log rank test between groups; $p = 0.02$) (Fig. 2). Newborns of erythromycin-treated women weighed more than those receiving placebo (erythromycin: $x = 1829.3 \pm 449$ gm; placebo: $x = 1624.4 \pm 398$ gm; $p = 0.3$).

Gestational age at enrollment was also similar between study groups for women ≥ 33 to 34 weeks' gestation at enrollment. There were no differences among treated ($n = 7$) or untreated ($n = 14$) women. Each of these women delivered within 10 days of rupture of membranes; more than 50% of both treatment groups delivered infants within 3 days of rupture of membranes.

Intrapartum and postpartum maternal and neonatal complications are shown in Table IV. There were no statistical differences between erythromycin- and placebo-treated mothers for measured outcomes. Chorioamnionitis was clinically diagnosed in seven (25%) erythromycin-treated women and six (22.2%) placebo-treated women. Most of these patients began labor spontaneously; three erythromycin-treated and one placebo-treated patients received oxytocin induction of labor. Postpartum endometritis occurred among two erythromycin- and one placebo-treated patients.

In addition to the erythromycin-treated patient who experienced the intrauterine fetal death, five erythromycin-treated women had infants who died during the neonatal period (Table IV). Each of these women had membrane rupture before 27 weeks' gestation (mean, 24 weeks). Four of these infants weighed between 630 to 870 gm at birth and died of complications of prematurity; the remaining infant (PROM at 26 weeks' gestation) delivered at 29 weeks' gestation (1270 gm) with clinical chorioamnionitis. This infant died of complications of prematurity 12 hours after birth. Conversely, among survivors, newborns of erythromycin-

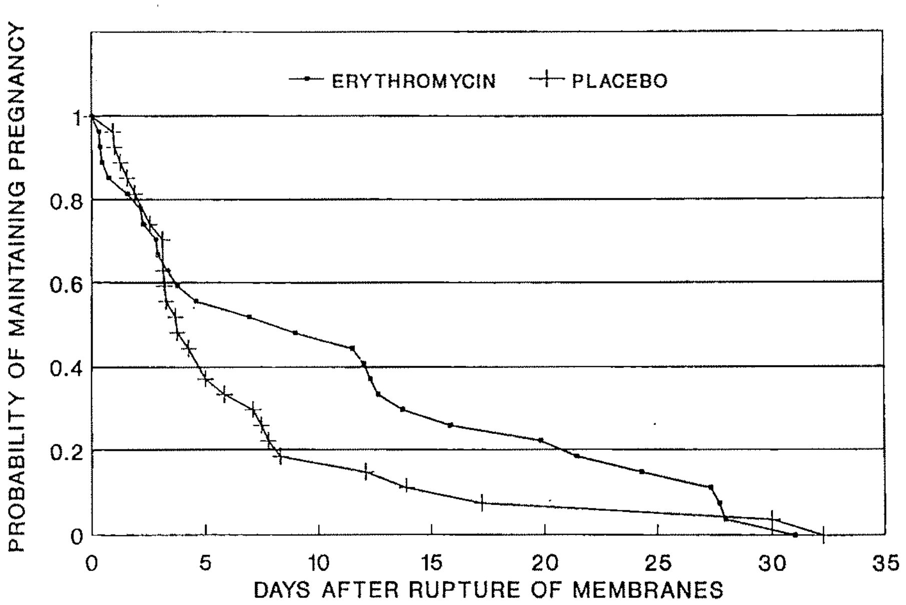

Fig. 1. Estimated risk of delivery after rupture of membranes for erythromycin- and placebo-treated patients. Log rank test between groups $\chi^2 = 0.94$, degree of freedom = 1, $p > 0.1$.

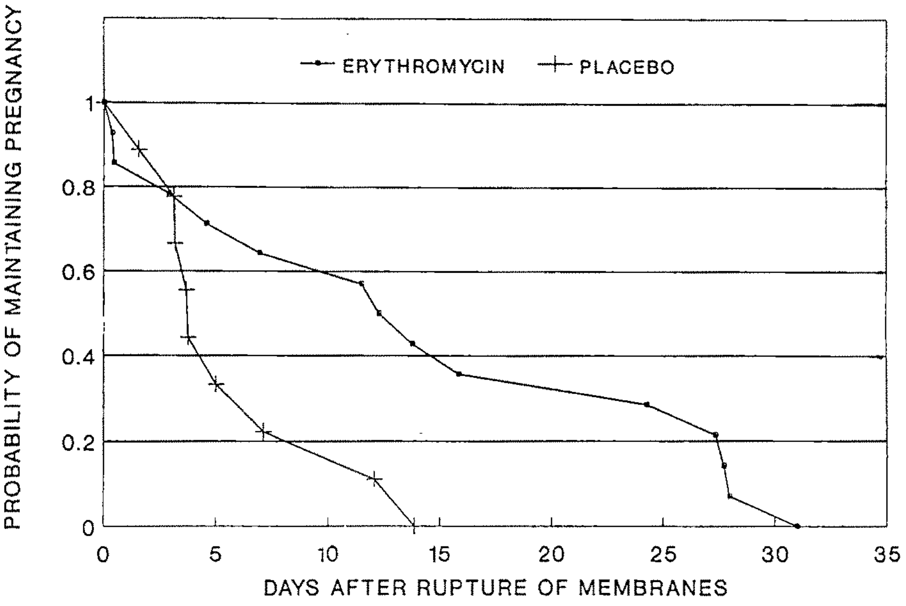

Fig. 2. Estimated risk of delivery after rupture of membranes between 28 to 32 weeks' gestation for erythromycin- and placebo-treated patients. Log rank test between groups $\chi^2 = 5.1$, $p = 0.02$.

treated women required fewer days of level II ($p = 0.07$) nursery care than those of placebo-treated women.

Both erythromycin and placebo were reasonably well tolerated; two patients who received erythromycin noted nausea and vomiting and transient diarrhea developed in one. No other maternal or neonatal sequelae were ascribable to use of erythromycin. No complications were noted among placebo-treated patients. In this relatively small trial, there were no differences for drug versus placebo-treated subjects based on microbiologic findings.

Comment

This study evaluated the efficacy, safety, and tolerance of a short course of oral erythromycin to prolong gestation and reduce the risk of perinatal and maternal morbidity among women with preterm PROM. Overall, erythromycin-treated women showed an increased, but statistically insignificant, time from study enrollment to

†$p = 0.07$.

onset of delivery compared with placebo-treated women (Table III). Treatment effects differed with gestational age at time of rupture of membranes: (1) erythromycin-treated women enrolled between 28 to 32 weeks' gestation had significantly prolonged interval from rupture of membranes to delivery (Fig. 2; $p = 0.02$); (2) erythromycin treatment of maternal-infant pairs with preterm rupture of membranes <28 or 33 to 34 weeks' gestation was not associated with benefit. Maternal morbidity and microbial findings did not differ between treatment groups. Among subjects who received erythromycin, there were more neonatal deaths ascribed to immaturity. Intraventricular hemorrhage also occurred more frequently among newborns in the erythromycin group (five versus one). Three of these newborns in the erythromycin group were delivered at ≤26 weeks' gestation and were among the neonatal deaths. Overall, there was no improvement in perinatal survival among newborns of mothers who received erythromycin (Table IV). In the erythromycin-treated group, surviving newborns required less level II care ($p = 0.07$). Erythromycin treatment was well tolerated.

Prior studies evaluating antibiotic use among women with preterm PROM are difficult to compare because they used varying antibiotic regimens, study designs, or failed to control for potentially confounding factors such as gestational age, use of tocolytic agents, or corticosteroids.[9-13] Ohlsson[3] reviewed these and other studies and concluded that antibiotics should not be used outside of a randomized, controlled trial, such as this study.

Given methodologic differences, our findings most closely support those of Amon et al.[12] In an unblinded, randomized study, Amon[12] noted significantly prolonged time from study entry to delivery among women with preterm PROM treated with ampicillin compared with women who were not treated; 49% of ampicillin-treated women compared with 26% of untreated women continued their pregnancy for 1 week after enrollment ($p = 0.05$). In this study 52% of erythromycin-treated women and 26% of placebo-treated women continued their pregnancy at least 1 week after study entry ($p = 0.05$). As in our study, Amon[12] noted no reduction in maternal morbidity among antibiotic-treated women. The results of Amon's study,[12] as well as our overall finding of consistent trends for pregnancy prolongation (Table III), strengthen our finding of significant ($p = 0.02$) pregnancy prolongation among erythromycin-treated women who entered the study between 28 and 32 weeks' gestation.

In another trial of antibiotic use among women with PROM, Morales et al.[13] reported significant reduction in the occurrence of clinically recognized intraamniotic infection and neonatal sepsis only among women vaginally colonized with group B streptococcus who received ampicillin. However, the period from rupture of membranes to delivery did not differ between ampicillin-treated and untreated women. Interpretation of this study is complicated because ampicillin treatment differed with microbial findings. In the present study, effects of the study drug could not be correlated with the presence of specific bacteria. Lebherz et al.[10] reported no benefit in terms of reduced neonatal morbidity, perinatal mortality, or antenatal infection among women who received tetracycline after preterm

PROM. Lebherz[10] did note a significant reduction in postpartum maternal infectious morbidity (most importantly urinary tract infection) in women who received tetracycline. Infectious morbidity was low in our patients.

Erythromycin base was chosen as the study antimicrobial in this trial because it is safe for use in pregnancy, reasonably well tolerated, and active against various microorganisms implicated in PROM and chorioamnionitis. Erythromycin inhibits bacterial protein synthesis and may prevent release of bacterial factors such as proteases and phospholipases that may play roles in PROM and preterm birth.[8] Further, erythromycin treatment was associated with prolonged pregnancy and increased birth weight among women experiencing idiopathic preterm labor with intact membranes in two randomized, double-blind trials.[18, 19]

Erythromycin is neither well absorbed across the placenta nor fully active within vaginal fluid. Conversely, erythromycin achieves relatively high concentrations in maternal uterine tissues and fetal membranes. These characteristics may help explain the lack of adverse effects, including superinfection, as well as the gestational age–linked effects of erythromycin noted in this study. As noted, erythromycin treatment did not appear to prolong the latency period among women with PROM occurring at 33 to 34 weeks' gestation. Recovery of group B streptococcus, *C. trachomatis*, and *S. aureus* was more common among these women. The presence of such acknowledged pathogens and possibly untreated subclinical amniotic fluid infections, may have contributed to early onset of labor, as suggested by Newton.[20] Alternatively, reduced time between rupture of membranes and delivery closer to term (>32 weeks' gestation) may reflect relative maturation of physiologic processes associated with parturition.

Similarly, erythromycin was of no apparent benefit when rupture of membranes occurred <28 weeks' gestation. Hillier and Eschenbach[5] found that microbiologic or histologic evidence of chorioamnionitis is most commonly associated with preterm birth at such low gestational ages. In this study, the excess number of subjects with very low gestational ages randomized to the erythromycin treatment group may have obscured any beneficial effect from a limited (1 week) course of antibiotics. Alternatively, it is possible that effects of inflammatory processes already in place at study entry cannot be mitigated by orally administered erythromycin treatment alone. The significant effect of erythromycin administration at 28 to 32 weeks' gestation in this study suggests that erythromycin treatment effectively addresses factors that play important roles in PROM and subsequent preterm birth in this clinically important middle ground.

Future investigations for treatment of preterm PROM may include revision of empiric antibiotic treatment based on the individual patient's microbiologic findings, adjunctive antiinflammatory therapy, or more prolonged antibiotic treatment. The sudden increased slope of the survival analyses (Figs. 1 and 2) occurring approximately 3 days after cessation of erythromycin treatment suggests that continued therapy beyond 7 days may be beneficial.

This double-blind, randomized, placebo-control study supports suggestions that selected antimicrobial therapy may benefit some women with preterm PROM by prolonging their pregnancy and allowing for further fetal growth and development. Future controlled treatment trials as well as microbiologic and pathophysiologic studies are required to confirm these findings in other populations and to further define patient selection criteria, mechanisms of action, and possible untoward effects of such antimicrobial treatment. Knowledge gained from such studies may provide improved treatment and possibly preventive strategies for preterm PROM, especially before 28 weeks' gestation.

We wish to acknowledge the editorial assistance of Cheryl Welch and Rosalyn Vu in manuscription preparation.

Expression and amplification of the HER-2/*neu* (c-*erb*B-2) protooncogene in epithelial ovarian tumors and cell lines

F.L. Tyson, PhD, C.M. Boyer, PhD, R. Kaufman, MD, K. O'Briant, MS, G. Cram, BS, J.R. Crews, MD, J.T. Soper, MD, L. Daly, BHS, W.C. Fowler, Jr., MD, J.S. Haskill, PhD, and R.C. Bast, Jr., MD

Durham and Chapel Hill, North Carolina

Amplification of the c-*erb*B-2 protooncogene has been associated with a poor prognosis in human breast and ovarian cancers. Our study was undertaken to examine whether amplification, rearrangement, or overexpression of c-*erb*B-2 and other protooncogenes was frequently observed in epithelial ovarian cancers. c-*erb*B-2 was expressed in 87% of 22 ovarian cancers analyzed, but expression was significantly increased in only one of the 22 tumor specimens. In this case elevated c-*erb*B-2 expression was associated with dramatic amplification of the gene. In another tumor a 3.8 kb *Eco*RI fragment was found, in addition to the usual 4.4 and 6.0 kb fragments; this is consistent with a possible gene rearrangement or a restriction fragment length polymorphism. To place these results in perspective, expression of several other protooncogenes has been examined in ovarian carcinomas. The c-*fos*, c-*myc*, n-*myc*, c-*fms*, and c-Ha-*ras* protooncogenes were expressed in different fractions of tumors, but expression of l-*myc*, c-*erb*B, c-*myb*, c-*sis*, and c-*mos* was not detectable. Aside from c-*erb*B-2, neither amplification nor rearrangement was observed among the other protooncogenes studied. Expression of c-*erb*B-2, c-*fms*, c-*myc*, n-*myc*, c-*fos*, and c-Ha-*ras* deserves further evaluation as a prognostic factor in ovarian cancer. (AM J OBSTET GYNECOL 1991;165:640-6.)

Cellular protooncogenes play a central role in growth regulation, and activated oncogenes have been implicated in the malignant transformation of cells. Activation of oncogenes may occur by several different mechanisms. Point mutations in deoxyribonucleic acid (DNA) can produce altered protooncogene products associated with a malignant phenotype. Overexpression of unaltered protooncogenes also can be associated with transformation. Increased gene expression can result from amplification of gene sequences or from translocation of gene sequences to a site where they come under the influence of new enhancers or promotors.

Activation of several different oncogenes may be required to produce malignant transformation, and coordinate activation of certain oncogenes may be particularly important. Products of different protooncogenes include growth factors, receptors for growth factors, guanosine triphosphate binding proteins, and nuclear binding proteins. Whereas the growth regulatory network is apparently tightly controlled in normal cells, activation of one or more oncogenes may result in uncontrolled proliferation and acquisition of a malignant phenotype.

Activation of certain oncogenes have been described in a variety of human cancers, but relatively few studies have been performed in ovarian cancer.[1-6] This study was initiated to determine which protooncogenes are expressed, amplified, or rearranged in epithelial ovarian carcinomas.

Methods

Tissues. Portions of fresh malignant tissues were obtained at Duke University Medical Center and at the University of North Carolina between 1985 and 1987, in accordance with procedures approved by the appropriate institutional review boards for handling pathologic material. Tissues were snap frozen in liquid nitrogen and stored at − 70° C until analyzed. Overall, 33 epithelial ovarian cancers were studied, including 19 papillary serous carcinomas, 6 papillary adenocarcinomas, 3 poorly differentiated adenocarcinomas, 2 clear cell carcinomas, 1 endometrioid adenocarcinoma, 1 mucinous adenocarcinoma, and 1 mesonephric carcinoma.

Cell lines. The breast and ovarian carcinoma cell lines were obtained and maintained as described previously.[7]

DNA probes and probe labeling. Probes obtained from the American Type Culture Collection (Rockville, Md.) included c-*mos* (ATCC 41004), v-*myb* (ATCC 41012), v-*sis* (ATCC 41033), v-*erb*B-1 (ATCC 41019), and v-*fms* (ATCC 41017). Additional probes were obtained from the Duke Comprehensive Cancer Center DNA Probe Library (c-Ha-*ras*,[8] c-*fos*,[9] c-*myc*,[10] n-*myc*[11], and l-*myc*[12], Dr. Mary Carrington (γ-actin[13]), and Dr. Matthias Kraus (National Cancer Institute, Bethesda) (pMac 30, c-*erb*B-2, HER-2/*neu*[14]). The c-Ki-*ras* 2 probe was obtained from Oncor (Gaithersburg, Md.). Probes were radiolabeled with phosphorus 32–deoxycytidine triphosphate (3000 Ci/mmol; Amersham, Arlington Heights, Ill.) according to the Multiprime DNA labeling system (Amersham) according to the manufacturer's instructions.

Isolation of ribonucleic acid (RNA) and DNA. Frozen tissues were ground to a fine powder in liquid nitrogen. RNA was extracted with guanidium isothiocyanate and isolated on gradients of cesium chloride. DNA was recovered from the interphase of the step gradient used for RNA isolation. DNA was digested with ribonuclease I and pronase, extracted with phenol-chloroform, precipitated with ethanol, and dissolved in 10 mmol/L Tris hydrochloride buffer with 1 mmol/L ethylenediaminetetraacetate, pH 8. RNA and DNA preparations were checked for degradation by gel electrophoresis, and any degraded samples were discarded. All samples analyzed for oncogene expression or amplification were positive when hybridized with a γ-actin probe.

Northern blot analysis. Total cellular RNA (25 μg) was analyzed by electrophoresis in 1% agarose formaldehyde gel, then transferred to nitrocellulose paper (Schleicher and Schuell, Keene, N.H.) or a Gene Screen (New England Nuclear, Boston) filter in a Northern capillary transfer. For RNA dot blot hybridization, RNA (10 to 20 μg) was serially diluted and applied to nitrocellulose paper with a vacuum blotting apparatus (Schleicher and Schuell). Filters were baked in a vacuum oven at 80° C for 2 hours and prehybridized at 42° C for ≥15 minutes with 50% formamide, 10% dextran sulfate, and 1% sodium dodecyl sulfate in 1 mol/L sodium chloride. Labeled probe (0.5 to 1.0×10^6 cpm/ml) and salmon sperm DNA (0.8 mg/ml) were denatured and added to the filter. After hybridization overnight at 42° C, filters were washed twice in 2 × saline–sodium citrate buffer (SSC) with 1% sodium dodecyl sulfate at 25° C, then washed three times in 0.2 × SSC with 0.1% sodium dodecyl sulfate at 60° C, and subsequently exposed to x-ray film (Kodak X-Omat AR, Eastman Kodak, Rochester, N.Y.) at − 70° C with one intensifying screen.

Southern blot analysis. Genomic DNA (10 μg) was digested with appropriate restriction endonucleases (Bethesda Research Laboratories, Gaithersburg), electrophoresed in 0.7% or 1 % agarose gels, and blotted on nitrocellulose paper or a Gene Screen filter in a Southern capillary transfer. For DNA dot blot hybridization, DNA (10 to 20 μg) was serially diluted and applied to a Gene Screen filter with a vacuum blotting apparatus. Prehybridization and hybridization of filters were performed essentially as described above for Northern blot analysis. Filters were washed twice in 2 × SSC at 25° C, twice in 2 × SSC and 1% sodium dodecyl sulfate at 75° C, twice in 0.1 × SSC at 25° C, and autoradiographed as described above.

Monoclonal antibodies. TA-1, a monoclonal IgG1 antibody reactive with the extracytoplasmic domain of c-*erb*B-2, was provided by Dr. Sara McKenzie at Applied Biotechnology (Cambridge, Mass.).[15] Mopc-21

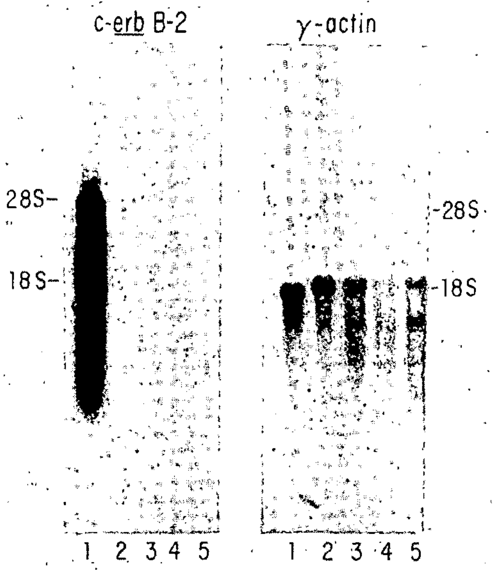

Fig. 1. Northern hybridization of ovarian carcinoma RNA. *Lanes 1 to 5* contain ICOV 46, ICOV 45, OV 111, OV 119, or ICOV 75 RNA probed with c-*erb*B-2 *(left panel)* or γ-actin DNA *(right panel)*.

c-*sis*	0/14	0
c-*erb*B	0/14	0

monoclonal IgG1 antibody (American Type Culture Collection, Rockville, Md.) was used as a control for nonspecific binding of immunoglobulin. Antibodies were used at a concentration of 5 μg/ml for radioimmunoassays and 0.5 μg/ml for immunohistochemical analysis.

Live-cell radioimmunoassay. The live-cell radioimmunoassay was modified slightly from the method of Greiner et al.[7] Statistical significance of differences in counts was assessed with the Student *t* test.

Immunohistochemistry. Frozen sections (4 to 6 μm) were stained as described previously.[16]

Results

Expression of c-*erb* B-2 protooncogene in epithelial ovarian cancers. Nineteen of 22 RNA samples (87%) isolated from epithelial ovarian cancers expressed c-*erb*B-2 by Northern blot analysis (Table I). The expected 4.4 kb c-*erb*B-2 transcript migrates just below the 28S ribosomal RNA band (Fig. 1). One tumor (ICOV 46) overexpressed c-*erb*B-2 RNA, although its expression of γ-actin RNA was comparable to that of other tumors (Fig. 1). Dot blot analysis of the same five tumor RNA samples indicated a 64-fold overexpression of c-*erb*B-2 RNA in the ICOV 46 tumor relative to the other tumors (Fig. 2). Five ovarian cancer cell lines derived from ascites fluid of patients with epithelial ovarian cancer and a B-lymphoblastoid cell line from one of the five patients were evaluated for expression of c-*erb*B-2 RNA by dot blot analysis. RNA isolated from the SKBr-3 breast cancer cell line, which overexpressed c-*erb*B-2 RNA, was included as a positive control. Among the ovarian cancer cell lines, OVCA 429 ex-

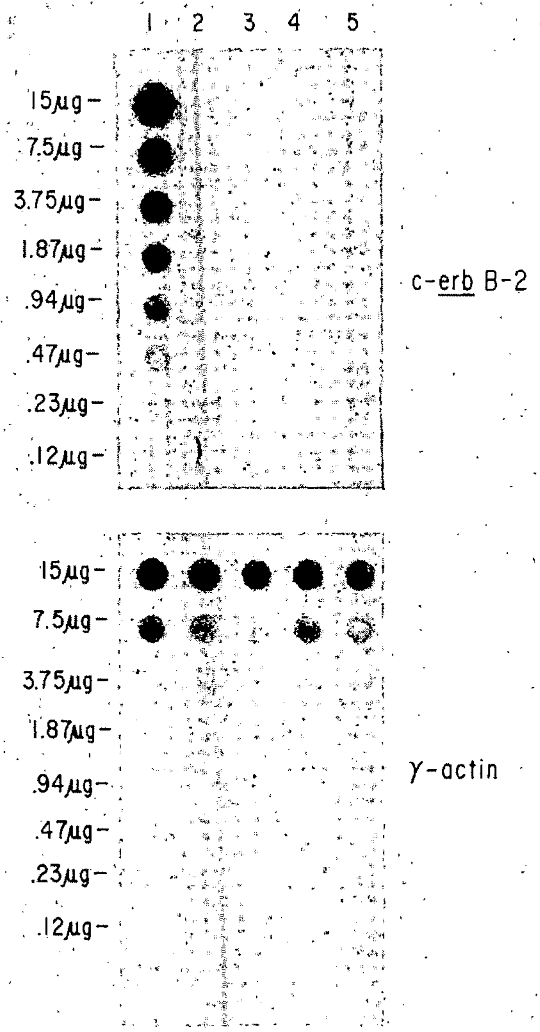

Fig. 2. Dot blot hybridization of ovarian carcinoma RNA. *Lanes 1 to 5* contain ICOV 46, ICOV 45, OV 111, OV 119, or ICOV 75 RNA probed with c-*erb*B-2 *(upper panel)* or γ-actin DNA *(lower panel)*.

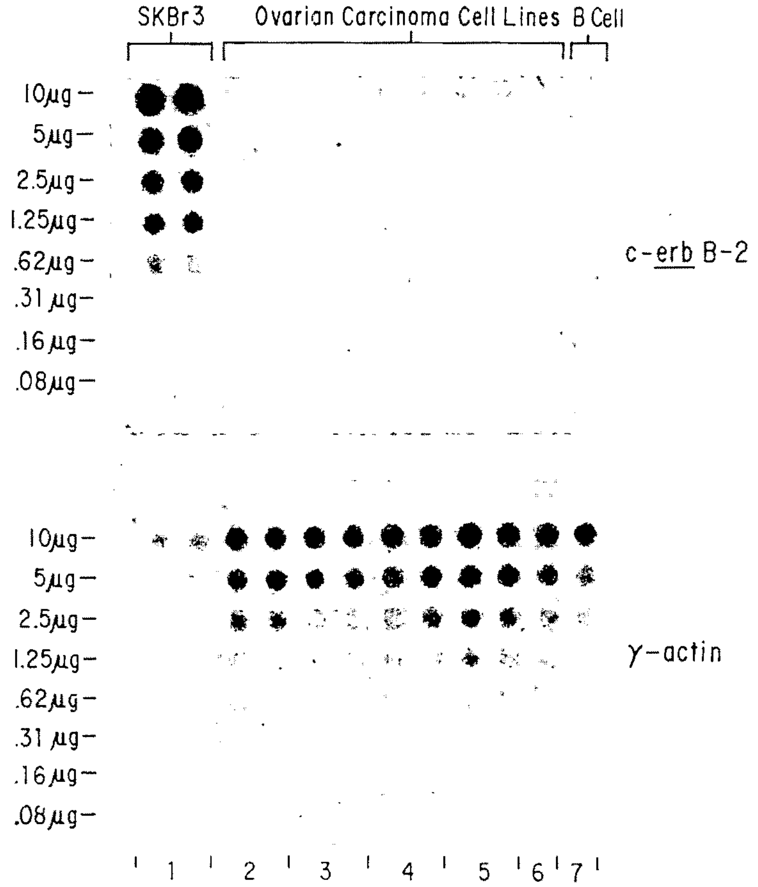

Fig. 3. Dot blot hybridization of breast and ovarian carcinoma cell line RNA. *Lanes 1 to 5* contain duplicate samples of SKBr-3, OVCA 433, OVCA 432, OVCA 420, or OVCA 429 RNA. *Lanes 6 and 7* contain single samples of ovarian cancer cell line DOV 13 and autologous B-lymphoblastoid cell line RNA, respectively. *Upper panel* was probed with c-*erb*B-2 DNA and *lower panel* with γ-actin DNA.

pressed the most c-*erb*B-2 RNA; however, the level of expression was 32-fold less than the level in SKBr 3 cells (Fig. 3). B-lymphoblastoid cell lines did not express detectable levels of c-*erb*B-2 RNA. RNA from each of the cell lines expressed comparable levels of reactivity with a γ-actin probe (Fig. 3).

RNA from epithelial ovarian cancers was also evaluated for expression of other protooncogenes by Northern blot analysis. In addition to c-*erb*B-2, the c-*fos*, c-*myc*, c-*fms*, and C-Ha-*ras* protooncogenes were expressed in a majority of the tumors tested. Expression of n-*myc* was found in one third of tumors. No hybridization was detected with probes for l-*myc*, v-*myb*, c-*mos*, v-*sis*, and c-*erb*B, although very low levels of these transcripts would not be discerned by Northern blot analysis of total cellular RNA (Table I).

Amplification of c-erbB-2 and other protooncogenes in epithelial ovarian cancers. DNA samples were isolated fom a total of 26 patients with ovarian cancer and evaluated for amplification of the c-*erb*B-2 gene by Southern blot analysis. In 13 cases DNA was obtained from samples that have been analyzed for expression of c-*erb*B-2 RNA. Amplification of c-*erb*B-2 was observed in DNA from one tumor (ICOV 46, Fig. 4). Dot blot analysis (Fig. 5) indicated a 64-fold amplification in the same tumor (ICOV 46) that had overexpressed c-*erb*B-2 on Northern transfers (Figs. 1 and 2). No amplification of c-*erb*B-2 DNA was detected in the ovarian cancer cell lines (data not shown). In each of 22 DNA specimens examined, neither amplification nor rearrangement was observed with any of the probes previously used for analysis of gene expression.

Restriction fragment length polymorphism of the c-erbB-2 protooncogene in epithelial ovarian cancer. The c-*erb*B-2 probe pMAC 30 generally hybridizes with two restriction fragments, 6.6 and 4.4 kb in length, in an *Eco*RI digest of DNA (Fig. 4). Hybridization with an additional 3.8 kb restriction fragment was observed with one tumor DNA (ICOV 21, Fig. 6), indicating a possible rearrangement of the c-*erb*B-2 gene. No c-*erb*B-2 polymorphism was evident when ICOV 21 DNA was digested with *Xba* I, or *Hin*dIII, rather than

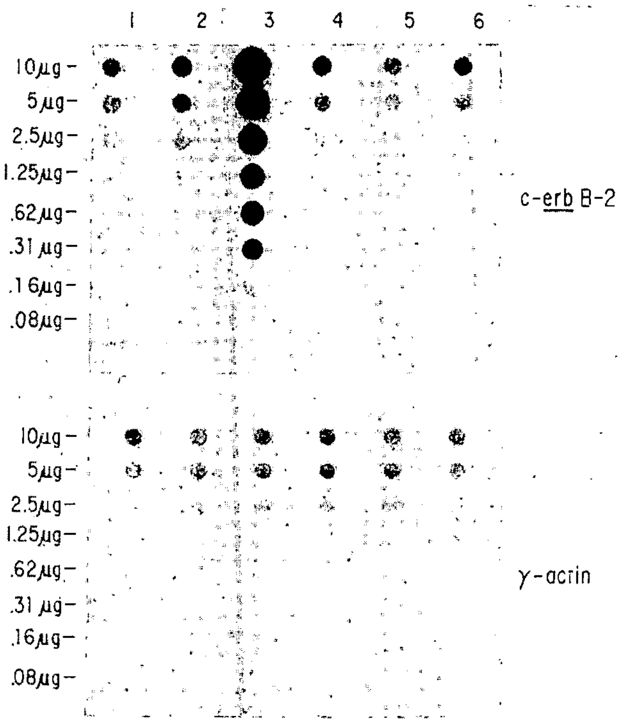

Fig. 5. Dot blot hybridization of ovarian carcinoma DNA. Lanes 1 to 6 contain ICOV 36, ICOV 43, ICOV 44, ICOV 46, ICOV 57, or ICOV 67 DNA probed with c-*erb*B-2 DNA *(upper panel)* or γ-actin DNA *(lower panel)*.

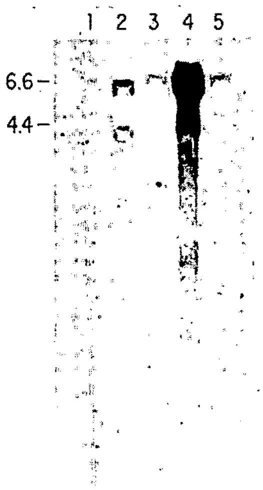

Fig. 6. Restriction fragment length polymorphism c-*erb* B-2 in ovarian carcinoma DNA. Southern hybridization of ovarian cancer DNA from ICOV 15, ICOV 21, ICOV 36, ICOV 46, and ICOV 57 in *lanes 1 to 5* probed with c-*erb*B-2.

*Eco*RI (data not shown). In another tumor DNA sample (ICOV 57), hybridization was observed only with the 6.6 kb restriction fragment, although both fragments were observed in normal DNA from the same individual (data not shown).

Detection of the c-erbB-2 protein in epithelial ovarian cancers. In a separate study[16] staining of frozen sections of normal and cancerous ovarian epithelium with the TA-1 anti-c-*erb*B-2 monoclonal antibody by the avidin-biotin immunoperoxidase method had been scored as no staining (0), light staining (1+), moderate staining (2+), or heavy staining (3+). Frozen sections of 13 tumors that had also been evaluated for expression or amplification of c-*erb*B-2 RNA or DNA were available for immunoperoxidase staining. All of the ovarian cancer tissues expressed c-*erb*B-2 protein. Two of 13 ovarian cancer tissues had light staining, two had moderate staining, and 9 of 13 had heavy staining, including ICOV 46.

Ovarian cancer cell lines were evaluated for surface expression of c-*erb*B-2 in a live-cell radioimmunoassay with the TA-1 monoclonal antibody. SKBr-3 and MCF-7 breast cancer cell lines were included as controls

Table II. Expression of c-*erb*B-2 protein in breast and epithelial ovarian cancer cell lines

		Antibody binding† (counts/min, mean ± SD)	
Cell line	*Mopc-21**	*TA-1**	*TA-1/Mopc-21*
SKBr-3	309 ± 46	2829 ± 121†	9.2
MCF7	292 ± 37	438 ± 50‡	1.5
OVCA 420	318 ± 65	593 ± 52‡	1.9
OVCA 429	252 ± 56	836 ± 164‡	3.3
OVCA 432	264 ± 24	310 ± 56	1.2
OVCA 433	336 ± 7	560 ± 83‡	1.7
Human fibroblast	281 ± 5	246 ± 46	0.9

‡$p < 0.05$, versus Mopc-21 control, Student *t* test.

that overexpressed c-*erb*B-2 (SKBr-3) or expressed normal levels of the protein (MCF-7). SKBr-3 cells bound nine fold more TA-1 monoclonal antibody than control Mopc-21 antibody, whereas MCF-7 cells bound 1.5-fold more TA-1 than Mopc-21 (Table II). OVCA 429 had the highest surface c-*erb*B-2 expression of the ovarian cancer cell lines (TA-1/Mopc-21 ratio, 3.3). Its RNA also had the most hybridization among the ovarian cancer cell lines with the c-*erb*B-2 probe by dot blot analysis (Fig. 3). Two additional ovarian cancer cell lines (OVCA 420 and OVCA 433) had surface c-*erb*B-2 expression comparable to that of MCF-7. One ovarian cancer cell line (OVCA 432) and a human fibroblast cell line did not bind signficant amounts of TA-1 antibody (Table II).

Comment

Overexpression of the c-*erb*B-2 (HER-2/*neu*) protooncogene has been associated with a poor prognosis in both breast and ovarian cancer.[5, 16-19] The reported incidence of c-*erb*B-2 gene amplification has ranged from 1 in 26 (4%) in our study to 31 in 120 (26%) in the study by Slamon et al.[5] Three additional reports described intermediate frequencies of c-*erb*B-2 amplification in ovarian cancers: 1 in 11 (9%),[1] 3 in 15 (20%),[20] and 1 in 5 (20%). Overall, in studies to date amplification of c-*erb*B-2 has been observed in 21% of 177 tumors evaluated. Some of the variation in observed frequency may be due to the small sample size in most of the studies. Another possibility is that the proportion of stromal cells might vary from tumor to tumor. Amplified c-*erb*B-2 sequences in epithelial ovarian cancer cells might be diluted by DNA of stromal cells that contain only single copies of the gene. Degradation of DNA or RNA also could affect the level of hybridization in Northern and Southern transfers, but the relatively low incidence of amplification and overexpression in our study was not due to this factor, since both DNA and RNA were tested for integrity before evaluation. All samples analyzed for oncogene amplification or expression contained intact nucleic acids, since they hybridized with a γ-actin probe.

Slamon et al.[5] found a complete correlation between gene amplification and overexpression of c-*erb*B-2 RNA or protein in breast and ovarian cancers. All of the tumors with amplified genes also were overexpressed. In addition, there was about a 10% incidence of cancers that had single-copy levels of the c-*erb*B-2 gene but also had evidence of overexpression by Northern blot analysis or immunoperoxidase staining. In our study c-*erb*B-2 DNA and RNA levels in the tumors were comparable, except for one tumor with marked amplification and overexpression of the gene. Immunoperoxidase staining of ovarian cancers, however, showed heavy staining for c-*erb*B-2 protein in the majority (9/13) of these tumors. In a larger study of 73 patients with ovarian cancer 32% of tumors exhibited increased levels of c-*erb*B-2 protein by immunoperoxidase staining.[16] Observation of increased levels of gene product in the absence of apparent amplification or overexpression of messenger RNA suggests that post-transcriptional regulation deserves further evaluation.

Only one restriction fragment length polymorphism, an additional 3.4 kb *Eco*RI fragment in one breast cancer, previously has been reported for c-*erb*B-2. Using a different probe we observed an extra 3.8 kb *Eco*RI fragment in one ovarian cancer, indicating either the creation of an additional polymorphic *Eco*RI site in a structurally normal gene or a possible rearrangement in or near the c-*erb*B-2 gene. In another patient the expected 4.4 kb *Eco*RI fragment was missing, indicating a possible deletion or point mutation in or near the c-*erb*B-2 gene.

A high frequency of expression of c-*myc* and c-*fos* was not unexpected because the expression of these protooncogenes is associated with proliferating cells. The $p62^{myc}$ product has been found to be expressed at higher levels in malignant ovarian cancer than in benign neoplasms or normal ovary. Although the c-Ha-

ras oncogene was expressed in half of the ovarian cancers tested, no overexpression or amplification was detected. Amplification of c-Ha-*ras* has been reported in 1 of 61 tumors (2%) studied by different investigators. Mutation of c-Ki-*ras* has been reported in a single case of ovarian cancer, and amplification was observed in 9 of 61 tumors (15%) studied to date.[2, 3]

The high frequency of expression of the *fms* oncogene in ovarian cancers is in agreement with data recently reported by Kacinski et al.[6] Macrophages also are known to express *fms*. The *fms* oncogene product is homologous to the receptor for macrophage colony-stimulating factor, a growth factor that stimulates monocytopoiesis and is a potent chemoattractant for macrophages. Of interest is that most ovarian cancer cell lines express macrophage colony-stimulating factor RNA and secrete macrophage colony-stimulating factor into culture medium. Thus the presence of a growth factor and its receptor in the same cells could provide autocrine stimulation of ovarian tumor growth or autocrine modification of cellular function. To date we have been unable to demonstrate stimulation of ovarian cancer cell growth with recombinant macrophage colony-stimulating factor. Alternatively, the paracrine growth regulatory mechanism might result from ovarian cancer cells that produced macrophage colony-stimulating factor, recruiting macrophages to the peritoneal cavity and tumor sites. Macrophage-derived growth factors could, in turn, stimulate ovarian cancer cell growth, as has been reported in murine sarcomas infiltrated with macrophages. We have observed that several macrophage-derived factors, including interleukin-1, tumor necrosis factor, interleukin-6, and an apparently novel factor, stimulate the growth of ovarian cancer cell lines. Identification of the components of this potential paracrine growth stimulatory loop in ovarian cancer may provide information useful in devising strategies for therapeutic intervention in ovarian cancer.

We thank Dr. Andrew Berchuck and Regina Whitaker for review of immunohistologic data and Dr. Matthias Kraus for valuable discussions and reagents.

Simultaneous measurements of prostacyclin and thromboxane metabolites during the menstrual cycle

Steven C. Presser, MD, Frank Z. Stanczyk, PhD, and Rogerio A. Lobo, MD
Los Angeles, California

The balance between prostacyclin and thromboxane is known to be important for reproductive and cardiovascular health but has been difficult to quantify. Whereas their stable urinary metabolites, 6-keto-prostaglandin $F_{1\alpha}$ and thromboxane B_2, may reflect in part systemic changes, it has been suggested that 2,3-dinor-6-keto-prostaglandin $F_{1\alpha}$ and 11-dehydro-thromboxane B_2 more adequately reflect systemic production. Therefore we report for the first time the simultaneous measurements of 6-keto-prostaglandin $F_{1\alpha}$, thromboxane B_2, 2,3-dinor-6-keto-prostaglandin $F_{1\alpha}$, and 11-dehydro-thromboxane B_2 during the menstrual cycle. Timed urine collections were obtained from 18 ovulatory women, aged 22 to 40, during the midfollicular and midluteal phases. Serum estradiol, progesterone, urinary pregnanediol glucuronide, estrone glucuronide, and creatinine also were measured. Prostanoid extraction from urine by C_{18} and silica Bond Elut columns were then separated by high-performance liquid chromatography before radioimmunoassay. Concentrations of all urinary prostanoids were not significantly different in the follicular phase when compared with the luteal phase. A positive correlation of borderline significance was noted between luteal thromboxane B_2 and pregnanediol glucuronide ($r = 0.70$) and between luteal estrone glucuronide and 2,3-dinor-6-keto-prostaglandin $F_{1\alpha}$ ($r = 0.68$). A significant correlation was found between follicular estrone glucuronide and the 6-keto-prostaglandin $F_{1\alpha}$/11-dehydro-thromboxane B_2 ratio ($r = 0.83$, $p < 0.04$). These novel normative data suggest an influence of sex steroids on prostacyclin and thromboxane metabolism. (AM J OBSTET GYNECOL 1991;165:647-51.)

Key words: Prostacylin, thromboxane, menstrual cycle, hormone mediated

Prostaglandins have been identified in every human reproductive tissue. Numerous previous studies with blood, endometrial tissue, menstrual fluid, or urine have measured prostaglandin E (PGE) and prostaglandin F (PGF) during the menstrual cycle.[1, 2] To date, however, only a small number of studies have assessed prostacyclin and thromboxane balance by the measurements of their respective stable metabolites, 6-keto-$PGF_{1\alpha}$ and thromboxane B_2.[3-5] Prostacyclin/thromboxane balance is considered to be important for normal vascular physiology and may be aberrant in abnormal states, ranging from pregnancy-induced hypertension[6] to atherosclerosis.[7]

Prostacyclin and thromboxane have been difficult to assess because these prostanoids are rapidly cleared from the blood due to their short half-lives. In addition, blood sampling with associated blood vessel trauma may result in artifactual increases mediated by platelet release and aggregation.[8-10] The measurement of urinary metabolites, which avoids the sampling problems associated with other invasive methods, is therefore considered to be the preferred method for assessing levels of prostacyclin and thromboxane.

Urinary 6-keto-$PGF_{1\alpha}$ and thromboxane B_2 are likely to reflect renal vascular tone, but it is uncertain whether they reflect systemic production.[11, 12] Their metabolites, 2,3-dinor-6-keto-prostaglandin $F_{1\alpha}$ and 11-dehydro-thromboxane B_2, are thought to reflect systemic production.[13, 14] Therefore we have developed assays for these metabolites and report for the first time the simultaneous measurements of 6-keto-$PGF_{1\alpha}$, 2,3-dinor-$PGF_{1\alpha}$, thromboxane B_2 and 11-dehydro-thromboxane B_2 during the menstrual cycle and how these metabolites correlate with estrogen and progesterone excretion.

Material and methods

Subjects and protocol. Eighteen healthy premenopausal women, aged 22 to 40 years (mean, 33 years),

From the Department of Obstetrics and Gynecology, Division of Reproductive Endocrinology and Infertility, University of Southern California School of Medicine.

Supported in part by a grant from Wyeth-Ayerst Research.
Presented in part at the Thirty-seventh Annual Meeting of the Society For Gynecologic Investigation, St. Louis, Missouri, March 21-24, 1990.
Received for publication September 13, 1990; revised March 4, 1991; accepted March 15, 1991.

Reprint requests: Rogerio A. Lobo, MD, Department of Obstetrics and Gynecology, Women's Hospital, Room 1M2, LAC+USC Medical Center, 1240 N. Mission Rd., Los Angeles, CA 90033.

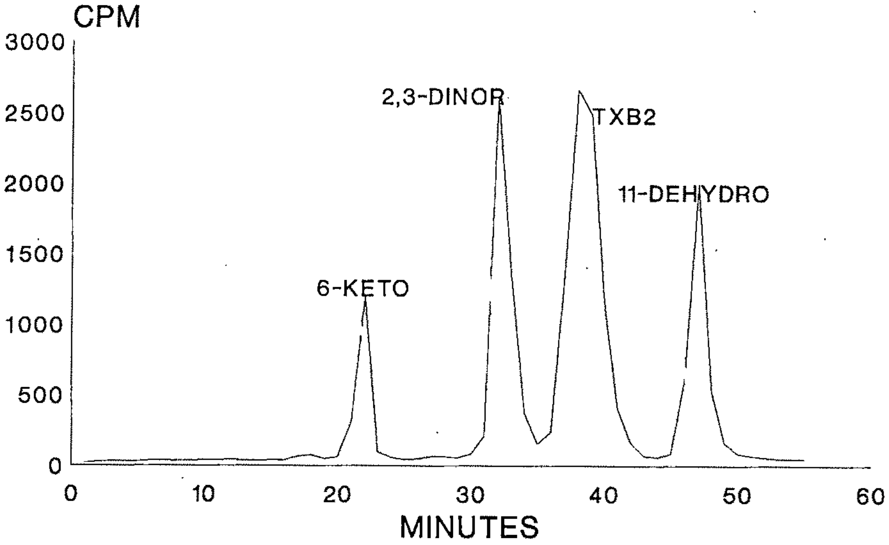

Fig. 1. Sample of high-performance liquid chromatography chromatogram for simultaneous separation of four prostaglandin metabolites, 6-keto-PGF$_{1\alpha}$, 2,3-dinor-6-keto-prostaglandin F$_{1\alpha}$, thromboxane B$_2$, and 11-dehydro-thromboxane B$_2$.

were recruited for the study. No subject had a history of significant illness (e.g., diabetes mellitus, hypertension, or cardiovascular, pulmonary, peripheral vascular, or renal disease). All women were within 20% of ideal body weight (mean, 136 pounds) and were nonsmokers. Subjects menstruated regularly with cycle lengths between 24 and 30 days (mean, 28 days). The cycle phase and ovulatory status were determined with the history of the last menstrual period and confirmed by a ratio of urinary pregnanediol glucuronide to creatinine (>2 $\mu g \cdot mg^{-1}$), as previously described.[15]

Subjects were asked not to consume aspirin, nonsteroidal antiinflammatory agents, or alcohol at least 2 weeks before or during the study period. In addition, no subjects had received any exogenous sex steroids within 60 days of the study. The women were studied in the midfollicular phase on days 5 to 9 ($n = 10$) or during the midluteal phase on days 19 to 24 ($n = 8$). Timed overnight urine samples were obtained and stored at −20° C until analyzed for the prostanoids. Simultaneous measurements of serum estradiol, progesterone, urinary pregnanediol glucuronide, estrone glucuronide, and creatinine also were obtained.

Assays

Prostanoids. Urinary 6-keto-PGF$_{1\alpha}$, 2,3-dinor-6-keto-prostaglandin F$_{1\alpha}$, thromboxane B$_2$, and 11-dehydro-thromboxane B$_2$ were measured by high-performance liquid chromatography radioimmunoassay (RIA) as follows: First, a 20 ml aliquot was obtained from an overnight urine sample, centrifuged to remove any sediment, and then acidified with formic acid to pH 3.5. Next, these internal standards were added to monitor procedural losses: approximately 4000 disintegrations/min of ^{3}H-6-keto-PGF$_{1\alpha}$ (Amersham Corp., Arlington Heights, Ill.; specific activity, 157 Ci/mmol); ^{3}H-2,3-dinor-6-keto-prostaglandin F$_{1\alpha}$ (Amersham; specific activity, 157 Ci/mmol; prepared by Brass et al.[16] and purified in our laboratory by high-performance liquid chromatography); ^{3}H-thromboxane B$_2$ (NEN Research Products, Boston; specific activity, 180 Ci/mmol); and ^{3}H-11-dehydro-thromboxane B$_2$ (Amersham; specific activity, 179 Ci/mmol), each in 0.1 ml of assay buffer. Prostanoids were then extracted from the urine with a sequential elution on a Bond Elut C$_{18}$ (3 ml) and silica (3 ml) column (Analytichem International, Harbor City, Calif.). Samples were then dried down with nitrogen at 40° C, and the residues were dissolved in 60 µl methanol.

Separation of the reconstituted sample was accomplished through chromatography, with a high-performance liquid chromatography system consisting of two model 501 pumps, a model 680 automated gradient controller, a model 481 variable wavelength detector, a model 712 Waters Intelligent Sample Processor, and a model 745 data module (Waters Associates, Inc., Milford, Mass.), and quantification of the separated fractions was achieved by RIA. Specifically, separation of 6-keto-PGF$_{1\alpha}$ (t_R [retention time] = 19.5 to 24.5 minutes), 2,3-dinor-6-keto-prostaglandin F$_{1\alpha}$ (t_R = 30 to 34 minutes), thromboxane B$_2$ (t_R = 35 to 40 minutes), and

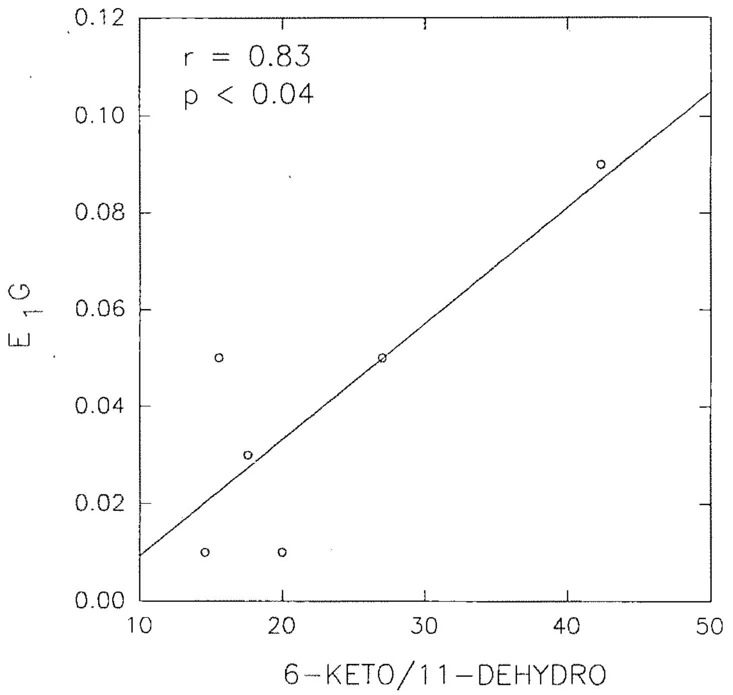

Fig. 2. Correlation of follicular urinary estrone glucuronide *(E_1G)* in micrograms per gram creatinine with 6-keto-$PGF_{1\alpha}$/11-dehydro-thromboxane B_2 ratio in nanograms per gram creatinine.

11-dehydro-thromboxane B_2 (t_R = 45 to 49 minutes) (Fig. 1) was performed through reverse-phase high-performance liquid chromatography with a programmed gradient prepared from water/trifluoroacetic acid (100:0.05, solvent A) and acetonitrile/trifluoroacetic acid (100:0.05, solvent B). Eluates were then evaporated under a vacuum by means of a vortex evaporator (Buchler Instruments, Fort Lee, N.J.). Prostanoid residues were then reconstituted in 0.7 ml buffer, and 0.2 ml aliquots in duplicate were taken for RIA; an additional 0.2 ml aliquot was taken for determination of procedural losses. The 6-keto-$PGF_{1\alpha}$ RIA uses ^3H-6-keto-$PGF_{1\alpha}$ (20,000 disintegrations/min) in conjunction with anti-6-keto-$PGF_{1\alpha}$ bovine serum albumin (final dilution, 1:100,000); the thromboxane B_2 RIA is carried out with anti-thromboxane B_2 bovine serum albumin (final dilution, 1:60,000) and approximately 20,000 disintegrations/min of ^3H-thromboxane B_2. The 2,3-dinor-6-keto-prostaglandin $F_{1\alpha}$ RIA uses the anti-6-keto-$PGF_{1\alpha}$ serum, which cross reacts with 2,3-dinor-6-keto-prostaglandin $F_{1\alpha}$ (10,000 disintegrations/min) in conjunction with ^3H-2,3-dinor-6-keto-prostaglandin $F_{1\alpha}$. Because 11-dehydro-thromboxane B_2 exists in cyclic and acyclic forms in a pH-dependent equilibrium, a specific buffer (0.2 mol/L Tris-phosphate hydrochloride, pH 9.2) was used to maximize the sensitivity and specificity of the RIA. In each RIA after a 16- to 18-hour incubation at 4° C, the free and antibody-bound prostanoids were separated by adding 0.6 ml of a dextran-coated charcoal (Norit A) suspension (0.5% [wt/vol]) and 0.05% (wt/vol) dextran. The antibody-bound fraction was then counted.

The intraassay coefficients of variation for 6-keto-$PGF_{1\alpha}$, 2,3-dinor-6-keto-prostaglandin $F_{1\alpha}$, thromboxane B_2, and 11-dehydro-thromboxane B_2 were 8.9, 10.0, 6.2, and 18.7, respectively, whereas the interassay coefficients of variation were 15.3, 6.6, 17.3, and 15.7, respectively.

Hormones. Estradiol, progesterone, pregnanediol glucuronide, and estrone glucuronide were all measured with established RIAs.[17]

Creatinine. Urinary creatinine was measured with the modified Jaffe reaction.

Statistics. Statistical analyses used two-sample *t* testing and regression analysis by the method of least squares. All results are reported as mean ± SE and calculated in nanograms per gram creatinine in the case of prostanoids.

Results

Prostanoid concentrations. Follicular and luteal phase estradiol levels were 66 ± 10 and 217 ± 29 pg/ml, respectively, whereas the respective follicular

Table I. Prostaglandin and thromboxane metabolites and their ratios in follicular and luteal phases*, †

*Mean ± SE.

†Values are in nanograms per gram creatinine.

and luteal progesterone levels were 0.17 ± 0.05 and 15 ± 3 ng/ml.

The concentrations of 6-keto-PGF$_{1\alpha}$, 2,3-dinor-6-keto-prostaglandin F$_{1\alpha}$, thromboxane B$_2$, and 11-dehydro-thromboxane B$_2$ and their ratios during the follicular and luteal phases are summarized in Table I. Concentrations of all urinary prostanoids were not significantly different in the follicular phase when compared with the luteal phase. All meaningful ratios between prostacyclin and thromboxane metabolites during the two phases of the cycle were calculated (data not depicted). No significant changes were noted.

When urinary prostanoids are compared with urinary pregnanediol glucuronide, a positive correlation of borderline significance was noted between luteal thromboxane B$_2$ and pregnanediol glucuronide ($r = 0.70$, $p = 0.07$) and between luteal estrone glucuronide and 2,3-dinor-6-keto-prostaglandin F$_{1\alpha}$ ($r = 0.68, p < 0.09$). In the follicular phase a significant positive correlation was evident between estrone glucuronide and the 6-keto-PGF$_{1\alpha}$/11-dehydro-thromboxane B$_2$ ratio ($r = 0.83, p < 0.04$) (Fig. 2). However, correlations between follicular and luteal 6-keto-PGF$_{1\alpha}$ and its stable metabolite, 2,3-dinor, or thromboxane B$_2$ and its metabolite, 11-dehydro-thromboxane B$_2$, failed to show significance ($r = 0.33, p = 0.5$; $r = 0.05, p = 0.9$; $r = 0.37$, $p = 0.3$; $r = 0.06$, $p = 0.9$, respectively).

Comment

Previous studies assessing prostaglandins during the menstrual cycle have focused on PGF$_{2\alpha}$ and PGE$_2$. We have presented for the first time a novel approach to the measurement of the stable metabolites of prostaglandins prostacyclin and thromboxane. These stable metabolites, 6-keto-PGF$_{1\alpha}$ and thromboxane B$_2$, and the 2,3-dinor and 11-dehydro metabolites have been simultaneously measured during the menstrual cycle.

In vivo and in vitro studies point to the role of estrogen in increasing prostacyclin biosynthesis and that progesterone decreases this apparently estrogen-mediated effect.[18-20] Recent evidence suggesting that prostacyclin production is significantly decreased in uterine arteries from postmenopausal women[21] further enhances this notion. Ylikorkala et al.[3] have shown an increase in 2,3-dinor-6-keto-prostaglandin F$_{1\alpha}$, using spot urine samples, from subjects given a regimen of oral contraceptive tablets containing desogestrel and ethinyl estradiol. No change, however, was noted in thromboxane B$_2$.

Prostacyclin, formed by the vascular endothelium, a potent vasodilator and the most powerful inhibitor of platelet aggregation, has had its uterine biosynthesis localized primarily to the myometrium.[22] It is reasonable to suggest that estrogen may increase prostacyclin and that this may influence blood flow to the myometrium. The precise function of thromboxane in the uterus, however, is unclear. Thromboxane, derived from platelets, is a proaggregator and powerful vasoconstrictor that can lead to the development of ischemia and uterine pain. In vitro studies indicate that it can stimulate the myometrium and all three muscle layers of the uterotubal junction to contract, thus increasing overall uterine tonus.[23]

The values we obtained for the various prostaglandin measurements are similar to those noted by other investigators.[24] The positive correlations of urinary estrone glucuronide to luteal 2,3-dinor-6-keto-prostaglandin F$_{1\alpha}$ and to the follicular ratio of 6-keto-PGF$_{1\alpha}$/11-dehydro-thromboxane B$_2$ are in keeping with the physiologic concept of hormone-mediated changes in prostaglandins. Also in keeping with these tenets is the positive correlation between luteal phase thromboxane and pregnanedial glucuronide. Liggins et al.[4] showed by using perifusion of human endometrial tissue during the menstrual cycle that the 6-keto-PGF$_{1\alpha}$/thromboxane B$_2$ ratio, which factored 6-keto-PGF$_{1\alpha}$ in the proliferative phase, favored thromboxane B$_2$ in the premenstrual phase. A possible role of thromboxane in limiting menstrual blood loss and preventing retrograde menstrual bleeding is also suggested by data that thromboxane may contract the fallopian tube and that platelets are present in menstrual blood.[23]

Although our study did not show any differences in 6-keto-PGF$_{1\alpha}$, 2,3-dinor-6-keto-prostaglandin F$_{1\alpha}$, thromboxane B$_2$, or 11-dehydro-thromboxane B$_2$ during the menstrual cycle, there was the suggestion, as noted, that changes in prostanoids occurred in association with hormonal fluctuations. Although previous work has suggested that 2,3-dinor-6-keto-prostaglandin F$_{1\alpha}$ and 11-dehydro-thromboxane B$_2$ urinary me-

tabolites may be more reflective of systemic production than either 6-keto-PGF$_{1\alpha}$ or thromboxane B$_2$, the metabolites of prostacyclin and thromboxane were similar during the menstrual cycle. This observation need not be contradictory in that we studied normal ovulatory women who did not have systemic disease. Further, the hormonal changes during the menstrual cycle are rapid and transient. More prolonged hormonal changes may be required to modify prostanoid secretion in the directions suggested.

This report therefore provides novel normative data on prostacyclin and thromboxane during the normal menstrual cycle, including the method for the simultaneous measurements of their stable metabolites. We are hopeful that this information will help provide a reference point for more investigation in this area.

We thank Dr. Eric P. Brass, Department of Medicine, Case Western Reserve University, Cleveland, for supplying us with the ^{3}H-2,3,-dinor-6-keto-PGF$_{1\alpha}$. The technical expertise of Clara Delgado also is gratefully acknowledged.

Recurrent mild abruptio placentae occurring immediately after repeated electroconvulsive therapy in pregnancy

David M. Sherer, MD,[a] Mary Lou D'Amico, RNC, BSN,[a] David P. Warshal, MD,[a] Robert A. Stern, MD,[b] Harold F. Grunert, MD,[c] and Jacques S. Abramowicz, MD[a]
Rochester, New York

We present a case in which electroconvulsive therapy was performed repeatedly in pregnancy because of severe depression with psychotic features and failure of chemical treatment. Each electroconvulsive treatment was immediately followed by uterine contractions and active uterine bleeding, possibly representing recurrent abruptio placentae occurring in association with the treatment. Transient acute episodes of maternal hypertension between 180/90 and 190/100 mm Hg, documented within minutes after application of each electroconvulsive treatment, might explain the abruptio placentae manifested by active uterine bleeding and uterine hyperstimulation. (AM J OBSTET GYNECOL 1991;165:652-3.)

Key words: Pregnancy, electroconvulsive therapy, abruptio placentae

The relative safety of electroconvulsive therapy in the treatment of certain cases of depression, mania, or psychosis in pregnancy has been reported in both obstetric and psychiatric literature.[1, 2] To the best of our knowledge, adverse outcomes with the application of this therapy in pregnancy have not been reported. We present a case in which repeated electroconvulsive therapy was performed in pregnancy. After each session of electroconvulsive therapy, mild abruptio placentae was suspected. We discuss the possible underlying mechanisms.

Case report

A 35-year-old Oriental woman, gravida 2, para 0, with one previous elective termination of pregnancy, was monitored during her second gestation. Her medical history was unremarkable. Gestational dating was based on last menstrual period and 9-week ultrasonography. The patient declined a genetic amniocentesis. At 19 weeks' gestation the patient began experiencing insomnia, anxiety attacks, and occasional suicidal thoughts. Treatment with oral diazepam, 5 mg three times a day, was initiated. Initially the patient responded. Ultrasonographic evaluation at 21 weeks revealed normal fetal anatomy and a low-lying posterior placenta. The patient's psychiatric condition deteriorated at 25 weeks' gestation with signs of worsening depression. After a suicide attempt at 26 weeks, she was hospitalized at an inpatient psychiatric hospital with a diagnosis of severe depression with psychotic features. Her condition remained unchanged, and antipsychotic therapy consisting of oral haloperidol (Haldol), 10 mg twice a day, was added. At 30 weeks, because of the intensity of delusions, severe anorexia, continued suicidal ideations, and advancing pregnancy, a decision was made to move directly to electroconvulsive therapy with the patient under general anesthesia and with continuous cardiotocographic monitoring. Before the electroconvulsive therapy, intravenous fluids were administered to avoid hypovolemia, and the blood pressure was 106/68 mm Hg. She was given oxygen by mask and intubated after intravenous thiopental sodium, 125 mg, and succinylcholine, 50 mg. Electroconvulsive therapy was performed with standard bilateral temporal electrode placement and a 30% energy setting (pulsed bidirectional square-wave stimulus with a fixed pulse width of 1 msec and a frequency of 70 Hz; Thymatron Somatics, Inc., Lake Bluff, Ill.), resulting in a seizure lasting 50 seconds. Immediately after the seizure, transient hypertension with pressures of 180/90 mm Hg was noted in conjunction with visible, palpable regular uterine contractions every 2 to 3 minutes. The fetal heart rate revealed reduced variability that was attributed to the intravenous thiopental sodium and was otherwise normal (Fig. 1). Uterine hyperstimulation (Fig. 1) was noted in conjunction with mild, bright red uterine bleeding. Gradually the bleeding and uterine contractions subsided. This regimen was performed on a weekly basis, with the same clinical picture after each session of electroconvulsive therapy. The uterine hyperstimulation noted after the electroconvulsive therapy at 31 weeks necessitated subcutaneous terbutaline, 2.5 mg. At 32 weeks' gestation Doppler velocimetric studies of the uterine and umbilical arteries were performed before, during, immediately after, and 10, 15, 20, and 30 minutes after the electroconvulsive therapy. Only minor changes were demonstrated in the systolic-

to-diastolic ratio, the pulsability index, and the resistance index of these vessels with higher values immediately after the electroconvulsive therapy. The electroconvulsive therapy at 34 weeks was followed by uterine bleeding to the extent that the patient required observation in the labor and delivery suite for 48 hours. Laboratory test results were normal, and a Kleihauer-Betke test gave negative findings. The bleeding subsided, and she was returned to the psychiatric hospital. A total of seven antepartum electroconvulsive treatments were performed. At 37 weeks the patient presented in spontaneous labor. At admission the cervix was dilated to 1 cm, with the fetal vertex presenting at the spine − 1 station. During labor, because of active uterine bleeding of approximately 800 ml, a transverse, low-segment cesarean section was performed with the patient under spinal anesthesia. A male infant weighing 2704 gm with Apgar scores of 3 and 9 at 1 and 5 minutes, respectively, was delivered. A large retroplacental clot was noted, confirming the diagnosis of abruptio placentae. The patient's postoperative course was unremarkable.

Comment

Previous reports have addressed the apparent safety and efficacy of electroconvulsive therapy for the treatment of depression in pregnancy. These reports failed to demonstrate any complications of labor and delivery or subsequent childhood growth and development.[1, 2] Eclamptic seizures are associated with major maternal and fetal morbidity and mortality. Although a tonic-clonic, grand mal–like seizure is caused by electroconvulsive therapy, it differs from eclampsia in that it is controlled: It is of shorter duration (seconds vs. minutes or longer), the patient is intubated and thus well oxygenated, and the fetus is continuously monitored. A transient increase in blood pressure is known to occur after electroconvulsive therapy. A previous report noting transient maternal hypotension after electroconvulsive therapy in pregnancy was thought to have been due to decreased intravascular volume.[1]

The association of abruptio placentae and hypertensive crises in pregnancy is well documented. We believe the uterine bleeding and uterine hyperstimulation, both manifestations of abruptio placentae, could possibly have been caused by the observed transient marked hypertension. These pathophysiologic events would be similar to those of abruptio placentae noted with acute hypertensive crises and cocaine abuse. Doppler velocimetric studies of the uterine and umbilical arteries might point to a slightly increased impedance to flow in the placental vasculature during electroconvulsive therapy. However, these changes cannot be attributed directly to electroconvulsive therapy itself and may well have been caused by the uterine contractions associated with the electroconvulsive therapy. In any event, although fetal distress did not occur, abruptio placentae in association with transient hypertension noted with electroconvulsive therapy emphasizes the importance of continuous fetal monitoring during this procedure.

Funic reduction for the management of umbilical cord prolapse

Jeffrey M. Barrett, MD
Lakeland, Florida

The current management of umbilical cord prolapse centers on attempts to alleviate the pressure of the presenting part on the cord while preparation for cesarean section is being made. A 10-year experience in which there were vigorous attempts to accomplish safe vaginal delivery after the diagnosis of umbilical cord prolapse is presented. Eight cases of umbilical cord prolapse occurred, a frequency of 1 in 277 deliveries (0.37%), all of which had a normal immediate neonatal outcome. Vaginal delivery was accomplished in seven patients (87.5%); diagnosis was made in two of them when delivery was imminent. Five patients were more remote from delivery and had successful funic reduction (manual replacement of the prolapsed cord). Funic reduction is proposed as a potentially beneficial initial step in the management of umbilical cord prolapse. (Am J Obstet Gynecol 1991;165:654-7.)

Key words: Umbilical cord prolapse, funic reduction, operative obstetrics

The management of umbilical cord prolapse currently centers on attempts to alleviate the pressure of the presenting part on the cord while the patient is being prepared for emergency cesarean section.[1, 2] All but forgotten has been the management of this potential catastrophe by aggressive attempts to achieve vaginal delivery, which was the management plan recommended in the era before attitudes about cesarean section became more liberal. Funic reduction, or manual replacement of the prolapsed umbilical cord, was once considered an appropriate initial step in the management of umbilical cord prolapse.[3, 4] This procedure was sometimes successful, but often delivery after this procedure resulted in an asphyxiated or stillborn neonate.[5] Because of the inability to predict outcome after funic reduction in the era before fetal monitoring, funic reduction was discarded in favor of emergency cesarean section.

The role of funic reduction in the management of umbilical cord prolapse has not been evaluated since continuous intrapartum fetal monitoring has been available. This article discusses my 10-year personal

experience with umbilical cord prolapse, in which funic reduction was used as an initial management step.

Material and methods

A review was performed that evaluated all private patients whose infants I delivered from July 1, 1980, until June 30, 1990. A total of 2188 deliveries occurred during the study period.

Patients who had had umbilical cord prolapse were reviewed for maternal age, gravidity, parity, cervical dilatation at the time of diagnosis, presence of ruptured membranes when the diagnosis was made, presence of decelerations of the fetal heart rate on fetal monitor before and after the diagnosis, type of delivery, type of anesthesia, gestational age, birth weight, Apgar score, umbilical arterial blood gas values, condition associated with umbilical cord prolapse, and whether funic reduction was attempted.

The diagnosis of umbilical cord prolapse was made by palpating the umbilical cord below the presenting part. When the diagnosis was made and delivery was not thought to be imminent, funic reduction was considered. This was performed by gently lifting the fetal head vaginally and digitally elevating the cord above the widest part of the fetal head in an attempt to place it in the nuchal area. Gentle abdominal pressure in the suprapubic area was simultaneously given to assist elevation of the fetal head and to decrease the chance of oblique or transverse lie. Continuous fetal monitoring was used during and after funic reduction. While this procedure was being performed, preparations for emergency cesarean section were being made.

Results

Eight cases of umbilical cord prolapse occurred, which was an incidence of 1 in 277 (0.37%). Table I describes the patients' characteristics and outcomes. In all cases the neonates were born alive and had normal 5-minute Apgar scores.

The single patient who required cesarean section was not considered to be a candidate for funic reduction, because the cervical dilatation was not felt to be adequate for that procedure. However, because there was no evidence of fetal distress on the fetal monitor, the patient was given an epidural anesthetic for the cesarean section. During the 52 minutes from diagnosis to delivery of the fetus, no abnormalities of the fetal heart rate tracing were noted.

The infants of patients 2 and 3 were delivered vaginally shortly after the diagnosis of umbilical cord prolapse was noted. Funic reduction was not attempted for either of these because, although neither fetus was crowning at the time of diagnosis, vaginal delivery was believed to be near. Patient 2 had severe variable decelerations of the fetal heart rate before the diagnosis of umbilical cord prolapse was made, but patient 3 did not have fetal heart rate decelerations until immediately before delivery.

Funic reduction was successfully accomplished immediately on diagnosis and without an anesthetic in each of the five cases in which it was attempted. None of the patients had ruptured membranes before admission to the hospital. All women in the funic reduction group had previously had one or more vaginal deliveries. The time period between funic reduction and delivery ranged from 14 to 512 minutes. Case 8 was actually a case of funic presentation but function-

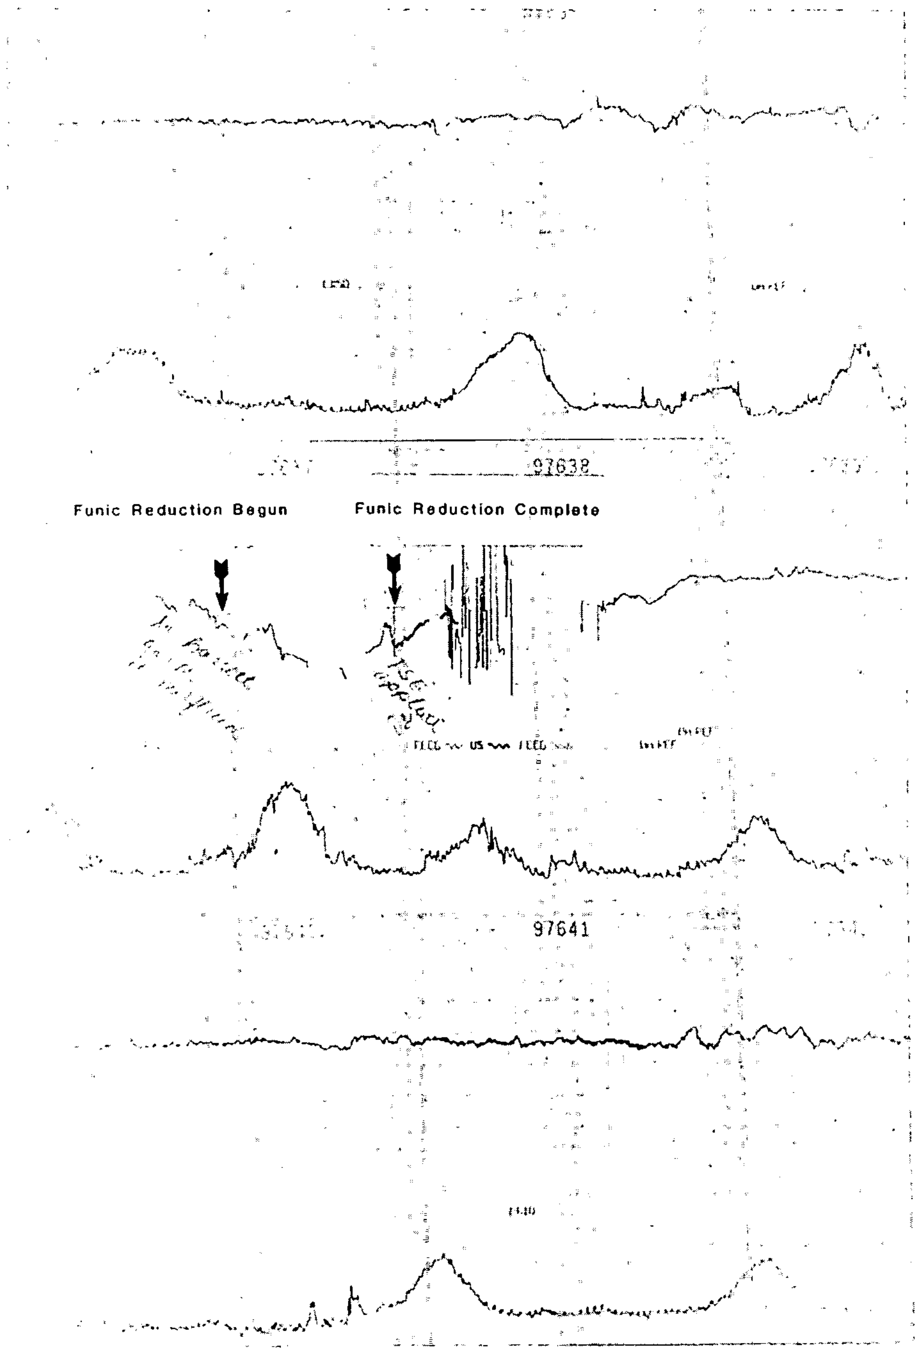

Fig. 1. Fetal monitor tracing before, during, and after funic reduction in case 6.

ally represented the same process as did the other cases.

Typically, a transient deceleration of the fetal heart rate that lasted from 3 to 5 minutes was associated with funic reduction (Fig. 1). In case 4 a second twin had repetitive severe variable decelerations during the 14 minutes between funic reduction and delivery. In case 5 mild variable decelerations occurred later in labor. The other three patients with funic reduction did not have subsequent variable decelerations. In cases 6 and 7 nuchal cords were noted at delivery.

Umbilical cord prolapse was thought to have resulted from iatrogenic causes in cases 6 and 7. In case 6 an amniotomy was performed when the vertex was at the − 1 station and the cervix was 6 cm dilated. In this case the stability of the fetal vertex at the − 1 station was misjudged, and with the leakage of fluid the vertex ascended slightly, allowing cord prolapse to occur.

Funic reduction was promptly performed. In case 7 unplanned rupture of membranes occurred during vaginal examination when the fetal vertex was at the −2 station, allowing cord prolapse.

Comment

In this report the frequency of umbilical cord prolapse was similar to that of other recent reports; however, the 12.5% cesarean section rate associated with umbilical cord prolapse was lower than in other reports, in which the cesarean section rate ranged from 70% to 96%.[2,6,7] In spite of this lower cesarean section rate, no neonatal deaths, no low 5-minute Apgar scores, and no delivery-related morbidity or mortality occurred.

The risk factors noted in this report are similar to those noted in other reports; they include prematurity, twin gestation, and artificial rupture of the membranes when the fetal presenting part was unstable. Breech presentation of the fetus, which is a risk factor for umbilical cord prolapse, was not noted. The absence of breech presentation as a risk factor for umbilical cord prolapse in this report is probably a result of allowing only women whose fetuses present as frank or complete breech to undergo a trial of labor.

Funic reduction was successful in each of the five cases in which it was attempted. In these cases only a relatively short segment of cord had prolapsed, and it is my opinion that funic reduction is much more difficult and perhaps inadvisable if a long (>25 cm) segment of cord is prolapsed. Funic reduction is also contraindicated if there is evidence of fetal distress on the fetal monitor. This procedure requires cervical dilatation that is adequate to place two fingers in the cervix (preferably dilatation ≥4 cm), the ability to elevate the fetal vertex above 0 station, patient cooperation, and gentleness on the part of the physician. It can be performed when membranes are intact. It is accomplished within 2 minutes, and any associated fetal heart rate deceleration is expected to resolve shortly after the procedure is accomplished. When funic reduction is successful, it is important to continuously monitor the fetus for evidence of cord compromise or other problems. While the procedure is being performed, simultaneous preparation for emergency cesarean section must be made. If it is not successful, other steps, such as elevating the fetal head with either manual pressure or bladder filling, as well as the use of tocolytic agents, should be undertaken until cesarean section is performed. If the umbilical cord reduction is successful, then the crisis can be resolved by the time the operating room is made ready for cesarean section, and the maternal and fetal risks of "crash" cesarean section (emergency cesarean section with a general anesthetic) can be avoided.

In this report the experience with funic reduction is clearly limited as a result of the small number of patients involved and the lack of a control group. These limitations are typical of an unplanned event that has a low frequency of occurrence and that is difficult to predict. Nonetheless, the uniformly good outcome in the five cases of umbilical cord prolapse that were managed with funic reduction suggests that, in carefully selected cases of umbilical cord prolapse and with the use of continuous fetal monitoring, this procedure can benefit the mother without undue risk of damage to the fetus. A larger-scale, controlled, modern reevaluation of this procedure to further assess the safety of funic reduction in the management of umbilical cord prolapse is recommended.

Adverse psychologic consequences of positive cytologic cervical screening

Caryn Lerman, PhD,[a] Suzanne M. Miller, PhD,[b] Ruth Scarborough, MEd,[c]
Parviz Hanjani, MD,[c] Susan Nolte, RN,[c] and David Smith, MD[d]
Philadelphia, Pennsylvania

Cervical cancer is still widely prevalent in the female population. This study explores the relationship of cervical cancer screening, positive versus negative Papanicolaou's test results, and psychologic status among lower-income minority women. All patients were interviewed 3 months after they had received initial test results. One hundred six women with normal Papanicolaou's test results were compared with 118 women who were referred for colposcopic examination for follow-up of positive test results. Women with positive Papanicolaou's-test results showed statistically significant elevations in worries about cancer and impairments in mood, daily activities, sexual interest, and sleep patterns. More fine-grained analyses revealed that the effects of positive results were most pronounced among those women who did not comply with colposcopy (n = 53). These findings suggest that lack of compliance with follow-up may maintain high levels of uncertainty about disease and may interfere with successful psychologic adaptation. Health education targeted to psychologically vulnerable individuals may reduce psychologic distress and enhance compliance. (AM J OBSTET GYNECOL 1991;165:658-62.)

Key words: Cervical screening, psychologic distress, compliance

In 1991 cervical cancer will develop in approximately 13,000 women; 4500 women are expected to die of this disease.[1] Morbidity and mortality rates remain highest among lower-income minority women, who tend to be underrepresented in screening programs for early detection of cervical abnormalities.[2] With improvements in patient and provider education, however, rates of cervical screening are increasing.[3] As a consequence, the detection of cervical intraepithelial neoplasia has risen markedly, particularly among younger women[4] and lower-income minority women.[5] This detection provides an opportunity for the prompt diagnositc follow-up and treatment of precursor lesions, which is essential to prevent invasive cervical cancer.[6]

On the other hand, analyses of the cost-effectiveness of cervical cancer screening programs have underscored the possible adverse psychologic impact on women who receive positive results.[7] It has been argued that the potential psychologic costs of participation might outweigh the medical benefits.[8] There have been anecdotal reports of significant psychosocial consequences of screening[9]; however, only one controlled study has been conducted.[10] In this follow-up of a mass screening for cervical cancer, women with positive results were found to exhibit moderate psychologic distress, but those effects were not long-lasting.[10] The potential of cervical screening to produce psychologic sequelae cannot be ignored because of the possible impact of such sequelae on patient compliance with subsequent screening and diagnostic follow-up.[9, 11] Patient compliance has been cited as a key determinant of the success or failure of cervical cancer detection programs.[12]

This study was designed to evaluate the psychologic effects associated with receiving positive Papanicolaou test results. Cervical cancer worries, mood, tension, and impairment in daily activities, sexual interest, and sleep were examined 3 months after the patients had received Papanicolaou test results. The relationship between adherence (i.e., whether follow-up colposcopic examination was completed) and these psychologic effects also was examined to determine whether such effects persist after cervical cancer has been ruled out. Information regarding the exact nature of psychologic sequelae, as well as the conditions that produce them, is critical if physicians are to manage adverse reactions in their high-risk patients.

Material and methods

Subjects. The subjects were 224 patients seen in the Family Planning Clinic and associated Colposcopy Clinic of Temple University Hospital. These clinics

serve the predominantly lower-income community of North Philadelphia. One hundred six women had normal Papanicolaou test results that did not require diagnostic follow-up. These women were compared with 118 women who were referred for colposcopic examination for follow-up of positive Papanicolaou test results. Among those with positive results, 65% complied with the scheduled colposcopy appointment. None of these women was found to have invasive cervical cancer. Subjects ranged in age from 15 to 58 years; the average age of the sample patients was 26 years. Demographic characteristics of respondents are shown in Table I. In accordance with the guidelines for human subjects experimentation, all respondents had provided oral consent to participate in this study.

Procedures. About 2 weeks after cervical screening, women received letters informing them about the results of their Papanicolaou tests. Women with positive results were informed that further testing was necessary. They also were notified that an appointment for a colposcopy examination had been scheduled. The date and time of the examination were stated with the clinic telephone number for rescheduling of the appointment, if necessary. Women who did not comply with the colposcopy appointment received a second letter emphasizing the necessity of follow-up and advising them to call the clinic to reschedule.

A brief (10-minute) structured interview was administered by trained telephone interviewers approximately 3 months after the patients had received Papanicolaou test results. This time period was selected to allow sufficient time for the scheduled diagnostic follow-up to rule out cervical cancer. All survey questions were forced-choice with Likert scale responses. Interviewers were blind to subjects' Papanicolaou test results. The response rate for these interviews was 70%; 26% of women could not be reached after four attempts, 2% of women were ineligible as a result of a language barrier, and 2% refused to be interviewed. The resulting sample of respondents included 224 women.

Measurements. Questions assessed respondents' sociodemographic characteristics (age, race, marital status, education, and employment status) and screening-sexual history (number of previous Papanicolaou tests, number of different sexual partners in the previous 3 months, and history of sexually transmitted disease). The following psychologic variables also were assessed: (1) current frequency of worry about cervical cancer (1 was never and 4 was often), (2) current impairment in daily activities as a result of cervical cancer worries (1 was never and 4 was often), (3) tension in the past month (1 was never and 4 was often), (4) mood in the past month (1 was very good and 5 was very bad), (5) sexual interest (1 was not impaired and 4 was impaired), and (6) sleep patterns (1 was not impaired and 4 was impaired). Mood and tension items were adapted from the Mental Health Inventory.[13] Other items were adapted from previous work on the psychologic impact of abnormal findings of mammography.[14]

Results

Demographic characteristics. As shown in Table I approximately 63% of respondents were aged 15 to 24

and 30% were aged 25 to 34. Eighty-four percent of respondents were black and only 11% were married. Most respondents (72%) had had at least a high school education, and 61% of respondents were currently employed. However, the lack of completed high school education and employment may, in part, reflect the young age of some of the respondents. According to χ^2 tests women who had positive test results were significantly more likely to be unemployed ($\chi^2 = 8.8$, $p < 0.005$) and to have had less formal education ($\chi^2 = 20.2$, $p < 0.001$). Women with negative results were significantly more likely to be black ($\chi^2 = 7.1$, $p < 0.005$).

Screening and sexual history. The majority of women reported that they had had previous Papanicolaou tests: 41% had had >10, 35% had had 5 to 10, and 34% had had <5. Ninety-two percent of women reported that they had had either no sexual partner or one sexual partner in the previous 3 months. Women in the different result groups (negative or positive result) did not differ significantly on these two characteristics. These groups did differ, however, with respect to their history of sexually transmitted diseases; 70% of women with positive results and 48% of women with negative results reported a history of at least one sexually transmitted disease ($\chi 2 = 11.0$, $p < 0.001$).

Factors associated with test result. Proportions of women with negative and positive test results who reported psychologic distress are shown in Table II. Thirty percent of the women with positive results reported that they often worried about cervical cancer, as compared with only 14% of women with negative results. In addition, 25% of women with positive results reported some impairment in their daily activities as a result of these worries, as compared with 11% of women with negative results. Fifty percent of women with positive results reported impairment in sexual interest and 40% had sleep disturbance, as compared with 31% and 26% respectively, among control patients. Student t tests were conducted to examine whether average ratings of psychologic responses differed significantly for women in the different test result groups. Women with positive results reported significantly more frequent worries about cervical cancer ($t = -3.01$, $p = 0.002$), more impairment in daily activities as a result of these worries ($t = -2.09$, $p = 0.02$), worse mood ($t = -2.20$, $p = 0.01$), more impairment in sexual interest ($t = -2.31$, $p = 0.01$), and more impairment in sleep ($t = -1.81$, $p = 0.04$). Between-group differences in tension were not statistically significant.

Multivariate analyses. Multivariate regression analyses were conducted for each of the five psychologic outcomes that exhibited significant bivariate associations with the test result. Demographic and sexual-screening history variables were included with the test result in the regression analyses to control for potential confounding influences on psychologic outcomes. To examine whether the effects of test results on psychologic outcomes were independent of compliance with follow-up, two-level index variables were created: (1) negative result versus positive result with subsequent colposcopy; (2) negative result versus positive result without subsequent colposcopy.

Women who had positive results but had not complied with colposcopy had significantly more frequent worries ($r = -0.21$, $p = 0.002$), more impairment in daily activities ($r = -0.20$, $p = 0.003$), worse moods ($r = -0.17$, $p = 0.01$), and more impairment in sleep ($r = -0.15$, $p = 0.03$) and in sexual interest ($r = -0.13$, $p = 0.01$) when compared with women who had negative results. By contrast, women who had positive test results but had undergone colposcopy differed from women with negative results in only two of these characteristics: impairment in daily activities ($r = -0.10$, $p = 0.004$) and in sleep ($r = -0.16$, $p = 0.03$). The effects of positive test results on psychologic responses were independent of all demographic and sexual-screening history confounder variables examined.

Comment

This study examined the psychologic impact of receiving positive results after cervical cancer screening in a population of minority women. Substantial and generalized negative psychologic consequences of a positive Papanicolaou test were observed 3 months after the patients had received test results. Not surprisingly, women with positive results exhibited heightened worries about cervical cancer and worsened moods when compared with women who had negative results. In fact, more than one third of women with positive results reported that they often worried about cervical cancer. In addition, these women reported greater impairment in daily activities and in sexual interest and sleep patterns when compared with women who had negative results.

More in-depth analyses revealed that these effects depended on the follow-up status of women who had positive test results. Women who had undergone colposcopy (65% of the sample) did not exhibit heightened worry or disturbance in mood or sexual interest when compared with women who had negative results. Completion of diagnostic follow-up may have reduced the uncertainty and uncontrollability surrounding a positive diagnosis, thereby ameliorating the negative psychologic sequelae of screening. In contrast, women who did not comply with colposcopy exhibited persistent distress and impairment. By not adhering to the recommended regimen, these women did not avail themselves of the opportunity to reduce distress by learning about the efficacy of early detection and treatment. This decision may create a vicious cycle in which failure to comply sustains uncertainty about disease and accompanying distress[15] that in turn contributes to delay in follow-up.

These results have implications for how health care professionals manage individuals in the course of cervical screening. Previous research suggests that proper education and counseling of women with positive Papanicolaou tests can improve psychologic status and can enhance compliance with follow-up. In a recent study, for example, women who received an informational leaflet along with postal notification of positive Papanicolaou test results were less anxious than were women who did not receive this additional information.[16] Such written communications about positive test results should highlight specific areas of patient concerns that may function as barriers to compliance, including cancer fears, loss of sexual-reproductive function, and aversion to medical procedures.[9] Indeed, mailings of written materials that bolster positive attitudes and address such barriers to follow-up have been shown to be a cost-effective mechanism for improving compliance.[17] This strategy may be supplemented profitably by more intensive efforts (e.g., structured telephone calls) for women who remain recalcitrant to follow-up. These educational messages should be targeted to women who are most likely to be lost to follow-up (those who are younger, unmarried, or of lower socioeconomic status.[18]

This study suffers from two main limitations. First, psychologic parameters were measured at a single time point 3 months after the patients were notified of these results. Therefore we cannot determine whether psychologic distress among noncompliers resulted from the uncertainty of their diagnoses or whether excessive psychologic distress predated and contributed to noncompliance. Prospective studies should evaluate, in a more fine-grained manner, patterns of patients' psychologic response and behavior during several key phases of the screening process. These include measures obtained before screening, while anticipating results, after notification, and during and after diagnostic follow-up and treatment. Second, the study population was predominantly younger, black, and less well educated. These findings therefore may not apply to the larger cervical screening population. On the other hand, this subpopulation constitutes the greatest risk group for invasive disease.[3] Ongoing research will help to pinpoint the role of psychosocial variables in contributing to avoidable cervical cancer morbidity and mortality in these high-risk populations.

We thank Ernestine Delmoor, Pat McGovern Gorchov, Irene Angel, and Bethel Taylor for their assistance in data collection and management. We also acknowledge Chris Combs and Craig Caputo for their contributions to data analysis.

Bound volumes available to subscribers

Bound volumes of the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY are available to subscribers (only) for the 1991 issues from the Publisher, at a cost of $61.00 for domestic, $88.27 for Canada, and $84.00 for international for Vol. 164 (January-June) and Vol. 165 (July-December). Shipping charges are included. Each bound volume contains a subject and author index and all advertising is removed. Copies are shipped within 60 days after publication of the last issue in the volume. The binding is durable buckram with the JOURNAL name, volume number, and year stamped in gold on the spine. *Payment must accompany all orders.* Contact Mosby–Year Book, Inc., Subscription Services, 11830 Westline Industrial Drive, St. Louis, MO 63146-3318, USA; phone (800) 325-4177, ext. 4351.

Subscriptions must be in force to qualify. Bound volumes are not available in place of a regular JOURNAL subscription.

Prospective evaluation of maternal serum human chorionic gonadotropin levels in 3428 pregnancies

Mark H. Bogart, PhD,[a] O.W. Jones, MD,[a] Robin A. Felder, PhD,[b] Robert G. Best, PhD,[c] Linda Bradley, PhD,[d] William Butts, PhD,[e] Barbara Crandall, MD,[f] Wendy MacMahon, BS,[g] Frank H. Wians, Jr., PhD,[h] and Paulette V. Loeh, BS[i]

La Jolla and Los Angeles, California, Charlottesville, Virginia, Columbia, South Carolina, Chandler, Arizona, Renton, Washington, Decatur, Georgia, and Lackland, Texas

As part of a multicenter prospective study, second-trimester human chorionic gonadotropin and α-fetoprotein concentrations were evaluated. Data included maternal age, human chorionic gonadotropin level, α-fetoprotein level, weight, race, and pregnancy outcome of 3428 pregnancies at between 15 and 20 weeks' gestation. The results of the study indicate that human chorionic gonadotropin levels decrease as maternal weight increases, that weight-adjusted human chorionic gonadotropin levels for Oriental and black women are higher than for white or Hispanic women, and that twin pregnancies have higher human chorionic gonadotropin levels than singleton pregnancies. Of 255 pregnancies that did not have normal outcomes, 54 (21.2%) had human chorionic gonadotropin levels >2.0 multiples of the median and 26 (10.2%) had α-fetoprotein levels >2.5 multiples of the median. Of 11 pregnancies with fetal aneuploidy, 6 (54.5%) had human chorionic gonadotropin levels >2.0 multiples of the median. It is concluded that in human chorionic gonadotropin screening programs for fetal Down syndrome, weight and race adjustments are necessary for accurate risk assessment. (AM J OBSTET GYNECOL 1991;165:663-7.)

Key words: Human chorionic gonadotropin, α-fetoprotein, Down syndrome, aneuploidy

The decision to prenatally screen pregnant women for fetal Down syndrome and other forms of aneuploidy has traditionally been made on the basis of maternal age. In recent years the use of combined maternal age and maternal serum α-fetoprotein concentrations (AFP) has become routine; it has recently been estimated that approximately 1 million pregnancies are screened according to these parameters.[1] There is widespread use of maternal serum AFP in spite of a combined maternal serum AFP and age detection rate of <40%.[2] In 1987 Bogart et al.[3] reported an association between abnormal human chorionic gonadotropin (hCG) levels and pregnancies with fetal aneuploidy. In that and subsequent studies it has been shown that elevated levels of hCG are associated with Down syndrome and other aneuploidies and that very low levels of hCG are associated with trisomy 18 syndrome pregnancies.[3-10]

All studies published so far are retrospective and include limited numbers of normal control pregnancies for comparison. Given the limits of the retrospective studies, the most effective proposed screening procedure is that described by Petrocik et al.[6] in which multiple regression probit analysis of hCG, maternal age, and maternal serum AFP values yielded a detection rate of 68.3% for 38 Down syndrome pregnancies, with a false-positive rate of 5%. Wald et al.[5] have published the largest data base, which includes 77 Down syndrome pregnancies with 60% detection at a false-positive rate of 6.7%. The false-positive rate was reduced to 4.7% when unconjugated estriol evaluation was included.

Our multicenter collaborative study was designed as a nonintervening prospective study to collect data on maternal serum hCG levels in a population that was already undergoing maternal serum AFP screening for neural tube defects. We collected data on hCG levels, maternal serum AFP levels, race, weight, age, pregnancy outcome, and karyotype results when amniocentesis was performed for other clinical indications.

Material and methods

Maternal serum samples were collected between 15 and 20 weeks' gestation as part of routine maternal serum AFP screening programs in seven geographically diverse areas: Arizona, California, Georgia, South Carolina, Texas, Virginia, and Washington. The number of patients enrolled in the study for each geographic region is presented in Table I. Patients were inter-

Washington	401
TOTAL	3428

viewed at the time of serum collection for information on maternal age, weight, race, family history of neural tube defects, and diabetes. Pregnancy outcome data were collected from patient records. These records include both reporting of outcome by patients and physician notes of pregnancy complications and abnormalities. Because there was no postdelivery follow-up by physicians, the possibility of underreporting minor abnormalities and abnormalities that are not apparent at birth cannot be ruled out. If amniocentesis was performed, karyotype results were also recorded. Gestational ages were determined by ultrasonographic evaluation when available or from the date of the mother's last menstrual period. Data were collected from 3428 pregnancies.

The β-hCG and AFP levels were assayed with commercially available enzyme immunoassays (Tandem-E hCG and Tandem-E AFP kits, Hybritech, San Diego). AFP assays were performed according to kit instructions. Kit standards for hCG are calibrated against the World Health Organization second international standard. Because of the high concentration of maternal serum hCG in the second trimester, serum samples were diluted in the diluent provided with the kits. Samples were diluted by hand or with a semiautomated diluter at 1:200 or 1:231. If an initial value was >375 mIU/ml or <10 mIU/ml, the sample was assayed again at appropriate dilutions. Samples were assayed twice, and any sample with a coefficient of variation >10% was assayed again. Interassay variation among all centers was 10.2%. Assay results from individual centers were further analyzed with Levene's test for equality of variance, Welch's test for equality of means, Bonferroni's test of significance between pairs of means, and the Student—Newman-Keuls multiple mean comparison test to confirm that the assay results could be pooled. These tests confirmed that the samples collected and assayed at the various locations could be pooled and analyzed as a group.

Results

Of the 3173 pregnancies that resulted in a normal outcome (defined as no birth defects or complications of pregnancy), 2505 mothers were white, 310 were black, 185 were Hispanic, 93 were Oriental, and 80 were of unidentified or other racial or ethnic groups. Table II describes the major categories of pregnancies that were not classified as normal. Of the 255 pregnancies that did not have normal outcomes, 112 involved abnormalities that were individually rarely observed or had not involved abnormal hCG or AFP levels. Percentages with elevated hCG levels (>2.0 multiples of the median value from normal pregnancies) or elevated maternal serum AFP levels (>2.5 multiples of the median) are also listed.

Median hCG levels for weeks 15 to 20 were calculated for the normal-outcome pregnancies of 2505 white women and are presented in Table III. Table III also presents the median hCG levels for normal-outcome pregnancies for black, Hispanic, and Oriental women.

Multiples of the median values for normal pregnancies in white women decreased as maternal weight increased. The following equation describes multiples of the median (MoM) as a function of maternal weight: MoM (corrected) = MoM/F, where $F = e^{[0.5145 - (0.00372 \times \text{weight in pounds})]}$.

The median weight of white women from Virginia (144 pounds) was elevated ($p = 0.064$) and the median weight of white women from Washington (135 pounds) was significantly less ($p = 0.006$) than the overall median (139 pounds).

In this study the median weights of white, Hispanic, Oriental, and black women were significantly different (Table IV). Statistical analysis indicated that there was no significant difference between the hCG levels of whites and Hispanics ($p = 0.56$) or whites and blacks ($p = 0.77$); however, the weight-adjusted multiples of the median of blacks were 9.8% higher than those of whites ($p = 0.008$) (Fig. 1). There was a significant difference between the hCG levels of whites and Orientals ($p = 0.0001$), and the weight-adjusted multiples of the median for Orientals were 16% higher ($p = 0.013$) (Fig. 1).

There were 33 twin pregnancies with normal outcomes and three twin pregnancies with abnormal outcomes (1 hydrops, 1 omphalocele, and 1 fetal death). The weight-adjusted median hCG level for the normal-outcome twins was 1.48 multiples of the normal singleton white weight-adjusted median hCG level, which is significantly elevated ($p = 0.002$).

The 11 pregnancies found to have chromosome abnormalities are listed in Table V. Six of the 11 had weight-adjusted hCG levels >2.0 multiples of the median (54.5%), including four of six pregnancies with Down syndrome (66.7%). The case of trisomy 20 mosaicism resulted in a normal female infant. Blood chromosome analysis did not reveal any trisomy 20 cells. This case most likely reflects confined mosaicism. Of

hCG values are before weight adjustment.

the white women with pregnancies having normal outcomes, 9.82% had weight-adjusted hCG levels >2.0 multiples of the median.

The median age of patients in this study was 28 years. There was no correlation between hCG values and maternal age (correlation coefficient = 0.028). There were insufficient data to determine any correlation between maternal diabetes and hCG levels.

Table IV. Median weights

Group	Median weight (lb)	No.	p*
White	139	2505	—
Hispanic	133	180	0.008
Oriental	115	90	0.0001
Black	147	310	0.0001

*Significance between median weights of white women and other groups ($p < 0.05$ is considered to be significant).

Comment

The results of this study indicate that maternal weight adjustment is needed in routine hCG screening for fetal aneuploidy. The weight-adjustment formula we developed for hCG values takes the same form previously described for maternal weight adjustment for maternal serum AFP evaluation[11] showing a decrease in median hCG levels with increasing maternal weight.

After weight adjustment, hCG levels from the normal singleton pregnancies of Oriental women were 16% higher than those for white women. However, because we evaluated hCG levels in the pregnancies of only 93 Oriental women with normal outcomes, further studies with larger numbers of Oriental women are needed before an accurate adjustment for Oriental-race factor can be calculated. It is interesting to note that the incidence of trophoblastic disease is greater in Orientals than in whites.[12] Whether the increased level of hCG contributes to or reflects a significant risk factor for trophoblastic disease should be the subject of further study.

Our results confirm the report by Petrocik et al.[6] that there is no statistically significant difference in hCG levels between white and black patients; however, this conflicts with a recently reported study in which significantly different levels were observed between these two racial groups.[13] On the other hand, we did observe a significant difference between the *weight-adjusted* multiples of the median for blacks and whites, with blacks having 9.8% higher weight-adjusted hCG levels. Although our data are taken from only 310 pregnant black women, it appears that the placenta of black

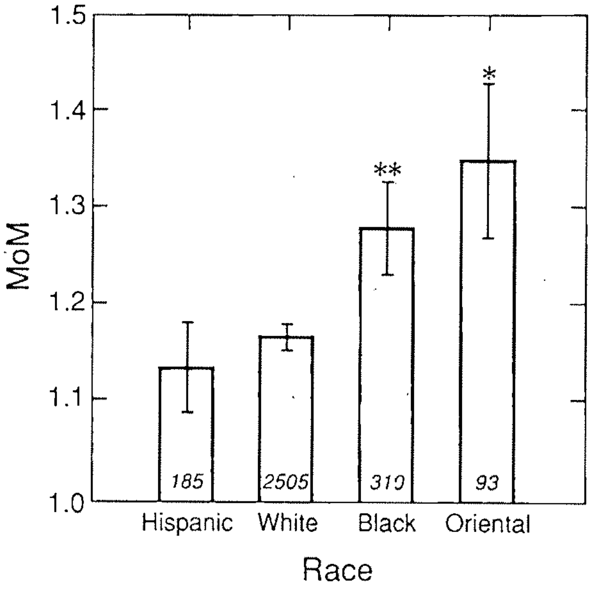

Fig. 1. Weight-adjusted multiples of the median (mean ± SEM) of different racial groups. Numbers within bars equal number of patients. *One asterisk,* Significance between white and Oriental women ($p = 0.01$); *two asterisks,* significance between white and black women ($p = 0.008$).

women produces 9.8% more hCG than the placenta of white women. Whether the increased amount of hCG is due to increased placenta size or increased production cannot be determined from this study. It is worth noting that the hCG levels recently reported for blacks by Simpson et al.,[13] using the same assay system that was used in our study, are nearly the same as we report for whites. It appears that the median hCG levels for whites in the study by Simpson et al., are less than the levels we observed. Such geographic variation in hCG levels in the pregnancies with normal outcomes of white women have previously been reported by Bartels et al.[14] and most likely reflect differences in maternal weight rather than a true difference in hCG production by the placenta. In this regard we observed a significantly lower weight in women enrolled in this study in Washington and a higher weight in women from Virginia. We believe that the use of weight-adjustment formulas is critical to accurate assessment of maternal hCG levels and that the use of such formulas is appropriate both for comparative studies and for clinical evaluation of Down syndrome risk. Additional factors such as smoking may also affect hCG levels[15, 16] and result in differences among subgroups within the population.

Although there is no documented difference in the incidence of fetal aneuploidy between different racial groups, screening programs that do not account for racial differences in weight, hCG production, and perhaps smoking habits may result in different detection and false-positive rates.

Our results indicate no correlation between maternal age and hCG levels; these results are consistent with previous reports[5, 6] and indicate that age and hCG levels are independent factors useful in screening for fetal aneuploidy.

Because of the increased placenta volume in twin as opposed to singleton pregnancies, the level of maternal serum hCG has been reported to be higher in twin pregnancies.[17] In our group of 33 twin pregnancies with normal outcomes, weight-adjusted hCG levels were significantly elevated ($p = 0.001$), with the median weight-adjusted hCG level approximately 1.5 times the singleton median.

In our study 6 of 11 pregnancies (54.5%) with fetal aneuploidy had abnormal hCG levels, including four of six pregnancies (66.7%) with Down syndrome (Table IV). These results are consistent with previous reports[3-10]; however, because of the limited number of cases of aneuploidy in this study, the statistical validity of the detection percentage is unreliable.

To more accurately evaluate the relationship between hCG, AFP, age, and aneuploidy, we have evaluated 49 Down syndrome pregnancies between 15 and 20 weeks' gestation using a probability risk calculation similar to that of Petrocik et al.[6] We observed a detection rate of 65.3%, with a false-positive rate of 7.85% (data not presented). This is quite similar to the findings of Petrocik et al. of approximately 68% detection at a 5% false-positive rate. Our false-positive rate is somewhat higher but is primarily based on gestational age estimation from the date of the mother's last menstrual period. It is well documented that approximately one third of women with abnormal maternal serum AFP levels have incorrect gestational age estimation when date of last menstrual period is compared with ultrasonographic evaluation.[18] Assuming that there is a similar occurrence in our study of one third of the women with abnormal hCG levels having incorrect gestational age estimates, our false-positive rate would drop to approximately 5.2% after ultrasonographic evaluation. Had this been an intervening study 7.8% of the women would have been referred for ultrasonographic evaluation, but only 5.2% would have had amniocentesis.

Screening programs can be expected to lead to the detection of approximately 65% of fetal aneuploidy, including Down syndrome, within the approximately 5% to 7% of women offered amniocentesis when calculation of combined-risk rates include evaluation of maternal age and hCG level. The findings of Wald et al.[5] and Petrocik et al.[6] indicate that addition of maternal serum AFP evaluation to hCG and age only minimally increases detection of fetal aneuploidy; however, the value of maternal serum AFP in detecting other types of abnormalities is well known. The addition of other biochemical parameters such as the gonadotropin α-subunit,[3, 4] unconjugated estriol,[5, 19] and pregnancy-specific β_1-glycoprotein (SP1)[20] for increasing detection of fetal aneuploidy have been proposed. There are conflicting claims regarding the value of unconjugated estriol[19, 21] and SP1,[14, 20, 22] and the findings of Bogart et al.[3, 4] on the free α-subunit have not been independently verified. Thus the value of these biochemical tests in addition to or as a replacement for maternal serum AFP in age-hCG-AFP risk evaluation for fetal aneuploidy remains to be proved. Decisions regarding the incorporation of one or more of the alternative biochemical tests depend on judgment of cost, accuracy, consistency, available assay systems, and ease of use. At this time there is insufficient evidence to determine which protocol is most efficacious. Regardless of conflicting claims regarding the addition of alternative biochemical tests, all screening protocols primarily depend on hCG evaluation. Thus it is important to establish baseline data on race differences, to establish weight-adjustment formulas, and to begin recognizing other pregnancy complications that are associated with elevated levels of hCG.

Fetal atrioventricular and outflow tract flow velocity waveforms during normal second half of pregnancy

Karin van der Mooren, MD,[a] **Leo G. Barendregt,**[b] **and Juriy W. Wladimiroff, MD, PhD**[a]
Rotterdam, The Netherlands

Maximum flow velocity waveforms at atrioventricular and outflow tract level were studied longitudinally in 40 fetuses from 18 to 38 weeks' gestation at 3- to 4-week intervals. Flow velocity parameters studied were peak systolic and time-averaged velocity and acceleration time at outflow tract level and time-averaged velocity, peak E-wave and peak A-wave velocities, and E/A ratio at atrioventricular level. An increase of all flow parameters with advancing gestational age was found. Aortic parameters were higher than pulmonary ones. Time-averaged, peak E-wave, and peak A-wave velocities were higher at tricuspid level than at mitral level, whereas E/A ratios were higher at mitral level. Outflow tract parameters showed no correlation with period time. A positive correlation for peak E-wave velocity and E/A ratio, and a negative correlation for time-averaged and peak A-wave velocity was found with period time. These results suggest that the normal second half of pregnancy is characterized by rising ventricular stroke volume and output and reduction in ventricular afterload. The left ventricular afterload seems to be lower than the right ventricular afterload. Atrioventricular flow velocities are heart rate dependent. (AM J OBSTET GYNECOL 1991;165:668-74.)

Key words: Fetal cardiac blood flow, Doppler ultrasonography, fetal heart rate

Transabdominal Doppler techniques can be used to determine flow velocities at the level of the human fetal heart from about 16 weeks' gestation onward.[1, 2] This allows information about fetal cardiac function to be obtained in a noninvasive way. Both cross-sectional and serial measurements of cardiac flow velocities at different gestational ages have been performed by several centers.[1-7] However, to our knowledge a detailed analysis of waveforms collected from all four fetal cardiac valves has never been carried out in a longitudinal setting. Moreover, few data have been published concerning the influence of variables such as fetal heart rate on fetal cardiac flow velocity waveforms.

The objective of the present study was twofold: (1) to establish the distribution of peak systolic velocity, acceleration time, and time-averaged velocity in the fetal cardiac outflow tract (ascending aorta and pulmonary artery) and time-averaged velocity, peak E-wave velocity, peak A-wave velocity, and E/A ratio at atrioventricular level (mitral valve and tricuspid valve) between 18 and 38 weeks' gestation; (2) to determine whether there is fetal heart rate dependency for one or more of the above parameters within the physiologic fetal heart rate range (i.e., 110 to 160 beats/min) and, if so, to establish the relationship between fetal period time (the reciprocal of heart rate) and the parameter concerned.

Patients and methods

A total of 40 women with normal singleton pregnancies consented to participate in the study. The study protocol was approved by the Hospital Ethics Committee. Fetal cardiac Doppler examinations were carried out at 3- to 4-week intervals between 18 and 38 weeks' gestation. The first examination was performed between 18 and 22 weeks' gestation.

Normal pregnancy was defined by a normal fetal biparietal diameter and birth weight between the 5th and 95th percentiles according to Kloosterman's tables, corrected for maternal parity and fetal sex.[8] The pregnancy duration was determined from the last menstrual period and confirmed by ultrasonographic measurements of the biparietal diameter between 14 and 18 weeks' gestation. The median maternal age was 29 years (range, 18 to 41 years), and the median parity was one (range, 0 to 6).

A combined mechanical sector scanner and pulsed Doppler system (CV 400, Diasonics, Milpitas, Calif.) with a carrier frequency of 3.5 and 3.0 MHz was used for blood flow velocity measurements in the ascending aorta, in the pulmonary artery, and at the mitral and tricuspid valves. The sector scanner operates at power outputs <100 mW/cm² spatial peak/temporal average

in both imaging and Doppler modes by manufacturer's specifications. Two-dimensional imaging was used to ensure the correct position of the pulsed Doppler gate, both before and after each Doppler tracing was obtained. Maximum flow velocity waveforms from the ascending aorta were recorded from the five-chamber view (Fig. 1). Maximum flow velocity waveforms from the pulmonary artery were collected from the conventional short-axis view (Fig. 2). Maximum flow velocity waveforms from the mitral and tricuspid valve were recorded from the four-chamber view (Fig. 3). At all sites the Doppler sample volume was placed immediately distal to the valve leaflets. The Doppler sample volume length ranged between 0.1 and 0.4 cm. Doppler tracings were accepted when the angle between the Doppler cursor and the assumed direction of flow was ≤10 degrees. Doppler studies were performed by one examiner (K.v.d.M.). All blood flow velocity waveforms were obtained during fetal apnea and stored on videotape. From hard copies the analysis of four consecutive waveforms was carried out with a microcomputer (M240, Olivetti, Scaramagno, Italy) linked to a graphics tablet. The following parameters were calculated: (1) in the two outflow-tract vessels—peak systolic velocity (centimeters per second), acceleration time (milliseconds), time-averaged velocity (centimeters per second), the ratios of these parameters at both sites, and the period time (milliseconds); (2) at atrioventricular level—time-averaged velocity (centimeters per second), peak velocities of E wave and A wave (centimeters

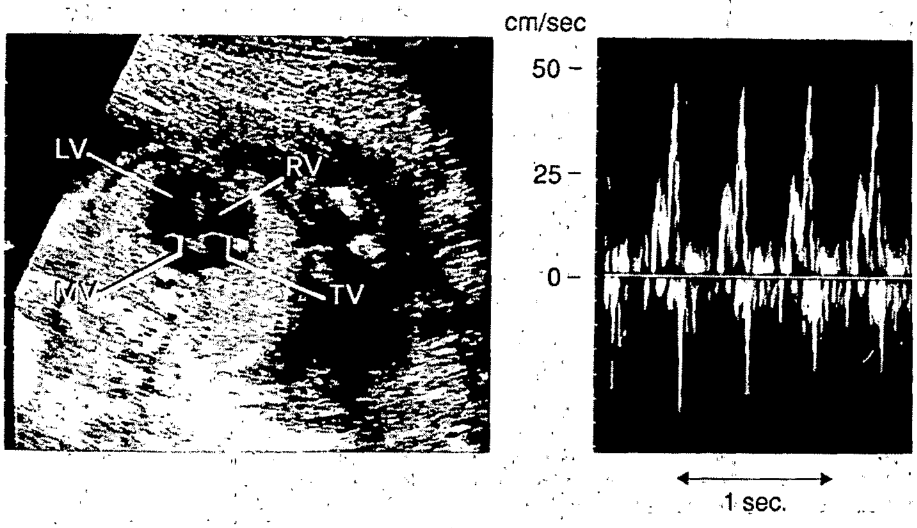

Fig. 3. Two-dimensional four-chamber view of fetal heart with Doppler flow velocity waveform tracing at tricuspid valve level at 21 weeks' gestation. *MV*, Mitral valve.

per second), E/A ratio, period time (milliseconds), and the ratio of tricuspid to mitral time-averaged velocity.

Peak velocities were measured from the 0 line to the highest point of the Doppler velocity peak. Acceleration time was measured as the time between the onset of ejection and the peak of velocity.[9] Time-averaged velocity was calculated as area under the curve divided by period time.

All Doppler studies were performed 2 hours after breakfast or lunch, with the patient in a semirecumbent position. The duration of one investigation never exceeded 30 minutes.

Statistical analysis included assessment of the relationship between all parameters studied and gestational age by repeated measurements analysis of variance, for which the BMDP program 5V (BMDP statistical software manual, volume 11, 1988, University of California Press, Berkeley) was used. The p values were determined by means of the sign test. The relationship between each parameter and fetal heart rate was studied as follows. For every patient the available data were interpolated in a linear fashion to a gestational age of 30 weeks, to rule out the influence of gestational age on the parameters. The reason for selecting 30 weeks was determined by the range of gestational ages (18 to 38 weeks) studied. For each adjusted parameter and period time the correlation coefficient was then calculated, and the corresponding p value was established. Left-to-right differences of the means per fetus were assessed with the paired t test. The lower level of statistical significance was set at 0.05.

Results

The success rate for obtaining good-quality flow velocity waveforms was 99% for the ascending aorta, 97% for the pulmonary artery, 99% for the mitral valve, and 97% for the tricuspid valve. In 4% of the mitral valve measurements and in 18% of the tricuspid valve measurements, it was not possible to separate E and A waves. This was more common with high-normal fetal heart rates. In these cases analysis of the waveform included only time-averaged and peak A-wave velocities. In each patient it was possible to obtain at least four serial recordings at all cardiac levels during the study period. On average, five investigations were performed in each pregnancy. Serial recordings of one particular valve or vessel were never longer than 6 weeks apart. In total, 233 studies were performed at a gestational age of 28.7 ± 5.8 weeks (mean ± SD). The relationship between any of the flow velocity waveform parameters and gestational age was approximately linear for each patient. It also appeared that the regression lines, by which the relation between parameter and gestational age for each of the patients could be described, differed significantly from patient to patient with respect to both the intercept and the slope. Therefore the following statistical model was adopted as the basis for the calculation of approximate 95% prediction bounds for each of the parameters, when the gestational age is known:

$$y = a + b(x - 30) + e$$

where y is the parameter concerned, x is the gestational age (weeks), a is the intercept of the regression line, b is the slope of the regression line, and e is an error term.

Thus for each of the parameters a regression line was constructed with its 2.5% and 97.5% confidence limits. The values for a, b, and e for each flow velocity waveform parameter, as well as the p values of the slopes, are listed in Table I.

Table I. Absolute values and standard errors of parameters determining regression lines for all flow velocity parameters with gestational age according to general formula $y = a + b\ (x - 30) + e$

Sa, Standard error of the intercept; *Sb,* standard error of the slope; *x,* gestational age

Period time in this study ranged from 361 to 535 msec, corresponding to a fetal heart rate of 166 to 112 beats/min, respectively. Average period time showed a significant increase with advancing gestational age, the regression equation being

$$y = 380.2 + 1.33x$$

($p < 0.0001$), where y is average period time (milliseconds), and x is gestational age (weeks).

In those fetuses in which it was not possible to separate E wave and A waves at mitral level, the average time period (± 1 SD) was 393 ± 20 msec, compared with an average of 425 ± 16 msec in fetuses with distinct mitral E and A waves. At tricuspid level these figures were 400 ± 22 and 423 ± 18 msec, respectively.

All parameters studied showed a significant increase with advancing gestational age. Peak systolic and time-averaged velocity, as well as acceleration time, showed higher values in the aorta compared with the pulmonary artery in most fetuses. The ratio for pulmonary to aortic peak systolic velocity did not change during the second half of pregnancy, with a mean ratio of 0.8 ± 0.0003 (1 SD). The ratio for pulmonary to aortic time-averaged velocity, however, increased with advancing gestational age ($p = 0.0005$), as did the ratio for pulmonary to aortic acceleration time ($p = 0.0001$). Time-averaged velocity and peak A-wave and E-wave velocities were higher at tricuspid level than at mitral level ($p < 0.0001$). E/A ratio was higher at mitral level than at tricuspid level ($p < 0.03$). The ratio for tricuspid-to-mitral time-averaged velocity did not change with advancing gestational age, the mean ratio being 1.097 ± 0.001 (1 SD). These results are also summa-

Table IIA. Mean left-to-right differences for ascending aorta and pulmonary artery, with their respective levels of significance

	Ascending aorta	*Pulmonary artery*	*Difference*		*p Value*

Mean acceleration time (msec)	58.5	48.5	10.0	4.3	<0.001

The figures are based on the mean paired differences per fetus (paired *t* test).

Table IIB. Mean left-to-right differences for mitral valve and tricuspid valve, with their respective levels of significance

	Mitral valve	*Tricuspid valve*	*Difference*		*p Value*
			Absolute	*SD*	
Mean time-averaged velocity (cm/sec)	16.9	18.5	−1.6	0.9	<0.001
Mean peak E-wave velocity (cm/sec)	33.2	37.2	−4.0	0.4	<0.001
Mean peak A-wave velocity (cm/sec)	47.0	53.6	−6.6	2.3	<0.001
Mean E/A ratio	0.71	0.69	0.02	0.007	<0.03

The figures are based on the mean paired differences per fetus (paired *t* test).

rized in Table I. In Tables IIA and IIB mean absolute differences (±1 SD) between all parameters for the right and left sides of the heart are presented with their corresponding level of significance. At the outflow tract level, no correlation could be demonstrated for any of the parameters and period times. The correlation coefficients at atrioventricular level are presented with their respective *p* values in Table III; negative correlations were found for time-averaged velocity and peak A-wave velocity at both sites. A positive correlation existed between period time and peak E-wave velocity, as well as E/A ratio.

Comment

In the human fetal heart, both right and left ventricles eject in parallel into the systemic circulation: the right ventricle into the ductus arteriosus and descending aorta; the left ventricle into the ascending aorta.[10] Therefore right and left ventricular output are not necessarily equal. In fact, many fetal echocardiographic studies are indicative of a distinctive right-heart dominance in the human fetus,[1, 2] although this is disputed by some.[11]

In this prospective, longitudinal study an increase with advancing gestational age was found for all flow parameters concerned. The distribution of the parameters increased toward term; this is in agreement with the increasing variance of biometric parameters with advancing gestational age. Fetal heart rate showed a significant decline toward term, as has been reported earlier.[4]

Cardiac performance is influenced by heart rate, preload, afterload, and intrinsic properties of both ventricles. From lamb studies it appears that cardiac function is particularly sensitive to changes in afterload,[12] which is determined by blood pressure and vascular resistance. The gestational age–related rise in normal peak systolic flow velocity and time-averaged velocity at semilunar level may be accounted for by increased volume flow through the semilunar valves, raised contractility, or reduced afterload. Age-related reduction in afterload may occur in the human fetus as a result of the physiologic decrease in placental vascular resistance, as expressed by increased end-diastolic flow velocities in the umbilical artery during the second half of gestation.[13] Peak systolic velocity correlates to some extent with time-averaged velocity. Volume flow is equal to mean velocity multiplied by area; therefore the observed increase in peak systolic and time-averaged velocity also may reflect increased left and right ventricular stroke volume and output. The noninvasive nature of human fetal Doppler studies does not allow differentiation between these explanations.

Calculation of volume flow was not attempted, because of the considerable error related to vessel and valve area measurements.[14] Therefore we cannot pro-

Table III. Correlation coefficients and *p* levels for relationship between period time and atrioventricular flow velocity parameters interpolated in a linear fashion to a gestational age of 30 weeks

	r	*p Value*
Mitral valve		
Time-averaged velocity (cm/sec)	−0.34	0.03
Peak E-wave velocity (cm/sec)	0.71	<0.001
Peak A-wave velocity (cm/sec)	−0.32	0.05
E/A ratio	0.67	<0.001
Tricuspid valve		
Time-averaged velocity (cm/sec)	−0.42	0.007
Peak E-wave velocity (cm/sec)	0.55	<0.001
Peak A-wave velocity (cm/sec)	−0.48	0.002
E/A ratio	0.59	<0.001

vide data concerning the presumed right ventricular dominance in the human fetus. The linear increase in peak systolic velocity in both arteries with advancing gestational age is in agreement with other studies, as are the absolute values.[1-4] Also, time-averaged velocity showed a linear increase with advancing gestational age. These data are in agreement with those presented by Kenny et al.[4] but are at variance with other reports in which no relationship between peak systolic[1] and time-averaged velocity[1, 6] and pregnancy duration could be established at semilunar level. The only explanation for these discrepant findings could be the fact that in the present study only flow velocity waveforms obtained at an interrogation angle of ≤10 degrees were collected. This is in contrast to the other reports in which interrogation angles up to 30 degrees were accepted.

The higher peak systolic and time-averaged velocities in the ascending aorta compared with the pulmonary artery observed in normal pregnancy may be due to the difference in semilunar valve area between the two vessels.[1] Alternatively, relatively low fetal cerebral vascular resistance with a subsequently lower left ventricular afterload may be responsible for the documented difference.[15] Of interest is that the acceleration time in the pulmonary artery was shorter than in the aorta, which is in agreement with a previous study by Machado et al.[9] Doppler echocardiographic studies on pulmonary hypertension in adults have demonstrated a close negative correlation between acceleration time and mean arterial pressure in the pulmonary artery as measured by cardiac catheterization.[16, 17] If a similar correlation is assumed in the normally developing fetus, the difference in acceleration time between the two outflow tract vessels would be in support of a different afterload in the two circuits.

In contrast to Machado et al.[9] we found an increase in acceleration time with advancing gestational age for both vessels. This is not surprising, since the afterload to both ventricles is determined mainly by placental vascular resistance, which is characterized by a fall during the second half of the pregnancy.[13] Moreover, both cerebral vascular resistance,[15] which is partly responsible for left ventricular afterload, and pulmonary vascular resistance[18] are subject to a reduction during the third trimester. This may explain the ratio increase with advancing gestational age for both pulmonary to aortic time-averaged velocity and acceleration time.

No correlation could be found between period time and any of the outflow tract parameters. This is in agreement with other observations, which show that only in cases of abnormally high or low fetal heart rates do the effects of the Frank-Starling mechanism become apparent.[19, 20]

Time-averaged velocity at tricuspid and mitral level increased with advancing gestational age with higher tricuspid velocities in nearly all fetuses, reflecting a rising ventricular output and/or decreasing afterload and/or improving myocardial contractility during the second half of pregnancy. Whereas similar results with slightly lower absolute values were reported by Reed et al.[6] and De Smedt et al.,[21] no such increase was established by Allan et al.[1] Peak E-wave and peak A-wave velocities, as well as E/A ratios, displayed a rise at both mitral and tricuspid level, with absolute values of peak A-wave and peak E-wave velocities being higher at tricuspid valve level. E/A ratios were higher at mitral valve level. The increase in peak E-wave velocity and E/A ratio suggests a shift of blood flow from late toward early diastole as a result of increased ventricular compliance with advancing gestational age. Similar observations have been made by others.[4, 6] Improvement in atrial contractility may be the cause for the rising peak A-wave velocities. The higher E/A ratios at mitral level again may reflect a relatively lower left ventricular afterload.

Our findings are partly at variance with those reported by others. Reed et al.[6] observed an increase of tricuspid peak E-wave velocity and a decrease of mitral peak A-wave velocity with advancing gestational age, while tricuspid peak A-wave velocity and mitral peak E-wave velocity did not show a significant change. Also, the absolute values were lower than observed in the present study. Hata et al.[3] reported an increase of both mitral and tricuspid peak A-wave velocity during the second and third trimesters but did not study peak E-wave velocities. At first sight these discrepancies seem quite impressive. The possible influence of the use of angle correction has been mentioned earlier. Moreover, none of these authors has taken into account the influence of period time on atrioventricular waveforms, which could explain, at least in part, the observed differences. In our study a negative correlation between peak A-wave velocity and time-averaged velocity and period time was established within the normal heart rate range at both atrioventricular valve levels. A positive correlation with period time for peak E-wave velocities and E/A ratios was found. This indicates that blood volume shifts from late to early diastole at lower fetal heart rates, thereby resulting in waveforms resembling those documented in older fetuses with more compliant ventricles.

The negative correlation between atrioventricular time-averaged velocity and period time may be explained by changing valve area, as has been suggested by Kenny et al.[22] This could be due to changes in ventricular filling. In conclusion, our results show that the normal second half of pregnancy is characterized by increasing flow velocities at both atrioventricular and outflow tract level, suggesting rising ventricular stroke volume and output and reduction in ventricular afterload. Flow velocity and acceleration time in the ascending aorta suggest a relatively lower afterload to the left ventricle. Transmitral and transtricuspid flow velocities are heart rate dependent.

Effect of cigarette smoking on maternal airway function during pregnancy

Tarun K. Das, PhD,[a] Jean-Marie Moutquin, MD,[a] and Jean-Guy Parent, MD[b]
Quebec City, Quebec, Canada

The effects of cigarette smoking on maternal airway function during pregnancy were investigated in a cross-sectional study of 97 smokers and 175 nonsmokers at different gestational ages. The groups were comparable in age, height, and weight. All subjects were healthy. Forced vital capacity, forced expiratory volume in 1 second, their ratio, the forced expiratory flow rates between 0.2 and 1.2 L, 25% and 75%, and 75% and 85%, and instantaneous flows at lung volumes of 25%, 50%, and 75% were measured. All spirometric tests were unaffected by gestational age. However, all parameters of spirometry were significantly less in smokers than in nonsmokers when cumulative data during pregnancy were compared. Forced vital capacity, forced expiratory volume in 1 second, and their ratio were minimally reduced (4%, $p < 0.05$; 8%, $p < 0.001$; and 4%, $p < 0.001$; respectively) in smokers as compared with nonsmokers. Larger reductions were noted in forced expiratory flow rates between 0.2 and 1.2 L (14%, $p < 0.001$) and between 25% and 75% (16%, $p < 0.001$), and in instantaneous maximum flows at lung volumes of 75% (11%, $p < 0.001$) and 50% (13%, $p < 0.001$). Maximum reduction of forced expiratory flow rates between 75% and 85% (26%, $p < 0.001$) and in instantaneous flows at maximum lung volumes of 25% (23%, $p < 0.001$) suggests marked increases in small-airway resistance and early small-airway disease in smokers. The progression of small-airway disease is related to the level of cigarette exposure. The results of our study demonstrate that the bronchodilatory effect expected in pregnancy is not sufficient to overcome the deleterious effects of cigarette smoking. (Am J Obstet Gynecol 1991;165: 675-9.)

Key words: Cigarette smoke, pregnancy, airway function

It has long been recognized that pregnancy can alter lung function and the natural history of certain pulmonary diseases. Although maximum flow rate and forced expiratory volume in 1 second (FEV_1) are not measurably altered,[1] the reduced total pulmonary resistance and increased airway conductance[2] observed during pregnancy suggest a bronchodilatory effect. This improvement in respiratory function is attributed to an increased concentration of progesterone, which is known to have a marked smooth-muscle–relaxing effect.[3] Indeed, progesterone has been given therapeutically to patients with obesity hypoventilation syndrome,[4] asthma,[5] and chronic obstructive pulmonary disease.[6] It could be hypothesized that the deleterious effects of smoking on airway function may be decreased during pregnancy, especially during the third trimester when progesterone levels are highest. Although cigarette smoking can cause airflow limitation in nonpregnant women,[7] little information is available on its effects on maternal airway function during pregnancy. This study was designed to assess the effects of cigarette smoking on airway function in normal pregnant women and to determine whether these effects are related to gestational age.

Material and methods

This was a cross-sectional study of women in each of the three trimesters of pregnancy who were recruited after written informed consent. The study was performed at the antenatal clinic of Saint-François D'Assise Hospital, a tertiary care teaching hospital associated with Laval University in Quebec City. Included in the study were women with nulliparous or multiparous singleton pregnancies who had no evidence of cardiopulmonary or obstetric disorders. Smokers had to abstain from smoking for ≥2 hours before the test. Subjects were excluded if satisfactory measurements could not be taken because of a lack of cooperation or an inability to perform the tests. Ex-smokers were retrospectively excluded because this group was too small to permit meaningful analysis. The study groups consisted of 97 pregnant smokers and 175 pregnant nonsmokers. Patients were grouped into three categories on the basis of gestational age: Group A (first trimester, 7 to 13 weeks) included 59 nonsmokers and 28 smokers; group B (second trimester, 14 to 26 weeks) included 56 nonsmokers and 35 smokers; group C (third trimes-

ter, 27 to 40 weeks) included 60 nonsmokers and 34 smokers. Each subject was studied as a member of only one gestational group.

Spirometric tests were conducted with a wedge bellow spirometer (Vitalograph Medical Instruments Ltd., Buckingham, England). Standard test methods were adhered to, with the patient in a standing position as recommended by the American Thoracic Society.[8] The spirometer was calibrated against a known volume of air with a precision syringe.[8, 9] Specific measurements of forced expiratory spirogram included forced vital capacity, FEV_1, FEV_1 expressed as a percentage of forced vital capacity ($FEV_{1\%}$), maximum expiratory flow rate ($FEF_{0.2\text{-}1.2\ L}$), maximum midexpiratory flow rate ($FEF_{25\%\text{-}75\%}$), maximum end-expiratory flow rate ($FEF_{75\%\text{-}85\%}$), and instantaneous flow (Vmax) at 75%, 50%, and 25% of remaining forced vital capacity. The expiratory efforts were maintained in most trials for 6 seconds. The best effort of three values within 5% or 100 ml of each other was used for the analysis. The maximum forced vital capacity and FEV_1 values were recorded, and flow rates were calculated from the curve with the greatest sum of forced vital capacity and FEV_1. All values were corrected for body temperature and pressure saturated with water vapor.

For each of the spirometric tests in both smokers and nonsmokers, the difference between means (±SD) was evaluated with the unpaired Student t test. One-way analysis of variance was also used for comparisons involving more than two groups. The relationship between smoking habit and lung function was assessed with multiple regression analysis. The alpha error for a significant test was set at the 5% level. The percentage of difference between the smoking and nonsmoking groups was assessed for each of the spirometric tests.

Results

The characteristics of the pregnant women are presented in Table I. The groups were comparable for age, height, and weight. Among smokers the daily consumption was 16.0 ± 6.55 (mean ± SD) cigarettes for a duration of 10.4 ± 3.76 (mean ± SD) years.

Table II illustrates the forced expiratory spirogram during the various trimesters for nonsmoking pregnant women. Forced vital capacity, FEV_1, $FEV_{1\%}$, $FEF_{0.2\text{-}1.2\ L}$, $FEF_{25\%\text{-}75\%}$, $FEF_{75\%\text{-}85\%}$, and 75% Vmax, 50% Vmax, and 25% Vmax were not affected by advancing gestational age. This was also the case in the smoking group (Table III).

When cumulative data during pregnancy were compared, the values of all spirometric parameters were significantly less among smokers as compared with nonsmokers (Table IV). More marked differences between groups were noted in both FEF and Vmax than in forced vital capacity, FEV_1, and $FEV_{1\%}$. The greatest differences were observed in $FEF_{75\%\text{-}85\%}$ and 25% Vmax (26% and 23%, respectively; $p < 0.001$).

The dose-response relationship between the level of

cigarette consumption and lung function is shown in Table V. The number of cigarettes smoked per day was directly related to the difference between the groups. This relationship was also confirmed by multiple regression analysis when adjustments were made for confounding variables such as age, height, and duration of smoking.

Comment

Airway function during pregnancy could be influenced by anatomic, hormonal, or biochemical factors. Progressive enlargement of the gravid uterus, mainly in the third trimester, may produce a restrictive effect. The reported reduction in alveolar Pco_2 in pregnancy, which is responsible for bronchial smooth-muscle constriction, can cause obstruction in airway function by increasing airway resistance.[10, 11] Our observation in both the nonsmoking and smoking groups showed no significant alteration in forced vital capacity, FEV_1, FEF, and Vmax at different lung volumes as pregnancy advanced; therefore there may be other mechanisms operating in pregnancy to oppose the expected alteration of airway function. Alternatively, those factors may have insufficient influence to modify the respiratory function as measured.

The results concerning forced vital capacity, FEV_1, and $FEV_{1\%}$ during the three trimesters in nonsmoking pregnant women are in agreement with previous studies in which serial measurements were performed.[12, 13] FEF and Vmax at different lung volumes have not been fully studied during pregnancy. In two studies,[1, 14] $FEF_{25\%\text{-}75\%}$, 50% Vmax, and 25% Vmax were measured and found to be unaltered during pregnancy; there were similar findings in our study. $FEF_{0.2\text{-}1.2\text{ L}}$, $FEF_{75\%\text{-}85\%}$, and 75% Vmax were also unchanged. There was no relationship between any of the studied parameters and gestational age. Preservation of airway function in the second half of pregnancy in spite of the enlarged gravid uterus may be caused by bronchodilating effects. Progesterone is known to have a widespread smooth-muscle–relaxing effect[3] and an increased β-adrenergic activity.[15] The relative mobility of the thoracic cage[16] may also be responsible for preserving forced vital capacity.

This is the first report of a significant decrease in airway function among pregnant smokers as compared with pregnant nonsmokers. Maximum reductions were seen in tests reflecting small-airway function. The decrease in forced vital capacity (4%, $p < 0.05$) could be explained by a narrowing or closure of the small air-

†16 to 30 cigarettes per day for 10.5 years.

ways, because 20% of forced vital capacity is thought to be related to these structures.[17] Loss of the elastic recoil pressure of the lung may also cause forced vital capacity to fall.

The reductions in FEV$_1$ (8%, $p < 0.001$) and FEV$_{1\%}$ (4%, $p < 0.001$) seen among smokers suggest an overall airway obstruction, although neither bronchoconstriction, compliance, nor recoil was actually measured. Because FEV$_1$ is a measure of flow rate during the first second of forced expiratory spirography, it includes sufficient flows at lower lung volumes to reflect small-airway changes in addition to large-airway changes.

The decreased flow at large lung volumes, such as FEF$_{0.2\text{-}1.2\ L}$ (14%, $p < 0.001$) and 75% Vmax (11%, $p < 0.001$) may be caused by either an increase in large airway resistance or a decrease in effort, inasmuch as these flows are largely effort dependent. Although subjects performed tests using maximum effort, a decrease in the expiratory muscle power among smokers cannot be entirely ruled out.

In contrast, FEF$_{25\%\text{-}75\%}$ and FEF$_{75\%\text{-}85\%}$ are independent of effort and are important to detect small-airway patency, particularly an airway with a diameter <2 mm. In smokers the contribution of small-airway resistance to total-airway resistance normally increases at low lung volumes, even when FEV$_1$ is not clinically abnormal. In the smoking group there was marked deterioration in both FEF$_{25\%\text{-}75\%}$ (16%, $p < 0.001$) and FEF$_{75\%\text{-}85\%}$ (26%, $p < 0.001$). A 25% reduction in FEF$_{75\%\text{-}85\%}$ is considered to be clinically abnormal[18]; however, the sensitivity of FEF$_{25\%\text{-}75\%}$ to dysfunction is not necessarily greater than that of FEV$_1$ because the FEF$_{25\%\text{-}75\%}$ has higher within- and between-individual variability.[19]

Although direct airway resistance and elastic recoil pressure or lung compliance were not measured, it is assumed that the observed decrease in flow rates at low lung volumes is caused by increased resistance to flow rather than a decrease in driving force. Alteration in lung elastic recoil after smoking cannot be entirely ruled out; however, in normal pregnant women lung elastic recoil should not be altered because lung compliance has been shown to remain unchanged during pregnancy compared with the postpartum period.[2]

The measurement of Vmax showed significant reductions in smokers. The maximum percentage of diffrence between smokers and nonsmokers was seen in 25% Vmax, suggesting early small-airway disease in smokers even though the subjects were asymptomatic. The relationship between the progression of small-airway dysfunction and smoking habits is confirmed by a direct relationship between the level of cigarette exposure and the degree of lung function loss. Further, there is a nicotine-induced increase in oxygen consumption with a reduced oxygen supply caused by carbon monoxide in smokers.[20] These factors could lead to a reduced supply of oxygen to the fetus. This reduced oxygen supply could contribute to intrauterine growth retardation.

In summary, changes in airway function in smokers during pregnancy were similar to those observed in nonpregnant smokers.[7] It can be concluded that the bronchodilatory effect expected in pregnancy is not sufficient to overcome the deleterious effect of cigarette smoking.

We thank Dr. William Fraser, MD, for his fruitful comments and Carmen Lindsay, BSc, Micheline Côté, RN, and Hélène Rolland for their assistance.

Effectiveness of antibiotic prophylaxis in preventing bacteriuria after multichannel urodynamic investigations: A blind, randomized study in 124 female patients

Kevin R. Baker, MD, Harold P. Drutz, MD, and Mary D. Barnes, RN, BA
Toronto, Ontario, Canada

One hundred twenty-four women with chronic, persistent lower urinary tract symptoms who had been scheduled for elective urodynamic investigations at Mount Sinai's Urodynamic Investigative Unit were divided into two blind, randomized groups, receiving either a placebo or prophylactic antibiotic. At the time of urodynamic testing, the rate of unsuspected urinary tract infection was 8.1%. There was no statistically significant decrease in postinstrumentation infection rate in the group who received prophylactic antibiotics. We conclude that, given in the fashion described in the study, prophylactic antibiotics are not effective in preventing urinary tract infections caused by urodynamic testing. (AM J OBSTET GYNECOL 1991;165:679-81.)

6/1/29603

Recent cases of bacteriuria after urodynamic investigations performed in the urogynecology unit at Mount Sinai Hospital prompted us to review the current literature and to question whether routine prophylactic antibiotics should be given after urodynamic testing. Previously, antibiotic prophylaxis was not routine in our investigative laboratory. Previous reports

have shown one-time bladder catheterization to result in a 2% incidence of urinary tract infection.[1] Bergman and McCarthy[2] reported a 4% incidence of acquired infection in a control group, compared with 0% in a treatment group. They concluded that this difference was not statistically or clinically significant because the numbers in each of the groups were small. They found a 7.3% incidence of unsuspected infection at the time of urodynamic evaluation; they suggested that a short course of prophylactic antibiotics before testing would be in order.

Similarly, Coptcoat et al.[3] found positive cultures in 2 (10%) of 20 women in a control group, compared with 0 (0%) of 18 women in a prophylactic antibiotic group. They concluded that antibiotic prophylaxis was not worthwhile in patients with normal upper urinary tracts undergoing cystometrography. However, Payne et al.[4] found that postinstrumentation bacteriuria developed in 10 (15%) of 66 women. This is not an insignificant number.

This prospective study was undertaken to assess the incidence of unsuspected bacteriuria before complete multichannel urodynamic testing and to assess whether antibiotic prophylaxis was effective in preventing significant bacteriuria after urodynamic investigations.

Material and methods

One hundred twenty-seven female patients with chronic, persistent lower urinary tract symptoms were asked to participate in the study during routine visits to the Mount Sinai Hospital's Urodynamic Investigative Unit. All patients had negative urine cultures before evaluation. Patients who were performing intermittent self-catheterization, were allergic to nitrofurantoin, or were receiving antibiotics were excluded from the study, leaving 124 women. Uroflowmetry and perianal electromyographic measurements with surface electrodes were performed with a DISA 2100 uroflow system (DISA Elektronic A/S, DK-2740, Skovlunde, Denmark). Urine specimens were obtained via catheterization immediately after uroflowmetry with a standard 14F catheter using sterile technique. The perineum was prepared with chlorhexidine (Hibitane gluconate 1:2000), followed by medium-flow water cystometry. The DISA 2100 urosystem was used to profile static and dynamic urethral pressure. Each patient was profiled in supine and standing positions; the 22K62 dual-pressure sensor microtip catheter with lumen was used in the bladder and urethra, and the 22K60 single-pressure microtip transducer was used in the vagina.

On completion of the procedures, the patients were randomly assigned to prophylaxis or nonprophylaxis groups according to hospital number. Both the physician and the nurse technician were blind as to which assignment the patient received. Patients in group A received nitrofurantoin 50 mg four times and phenazopyridine hydrochloride 200 mg three times for 1 day. Patients in group B received phenazopyridine hydrochloride only. The code was broken at the completion of the study. A clean-catch urine specimen was obtained for culture and sensitivity testing 2 to 3 days after urodynamic testing.

For the purposes of this study, infection on initial catheter-specimen urine is defined as growth $>10^6$ colony-forming units per liter. For the follow-up clean-catch midstream urine, infection is defined as $>10^8$ colony-forming units per liter.

Methods, definitions, and units conform to the standard recommended by the International Continence Society,[5] except where specifically noted. Statistical analysis consisted of Student's t test (two-tailed) or χ^2 (with Yates' correction for continuity) where applicable.

Results

A total of 124 women were recruited for the prophylactic antibiotic trial. All had recently provided sterile midstream urine specimens before recruitment. Of the 124, 22 did not complete the study: 12 women did not provide posttreatment urine specimens, 8 had initial catheter specimens that tested positive for urinary tract infections, and 2 fell into both categories.

Ten (8.1%) of the 124 women had catheter-specimen urine that tested positive for infection before urodynamic testing, thus giving an unsuspected urinary tract infection rate of 8.1%.

The remaining 102 women were examined for differences in infection rate. Table I lists the demographics of both groups; there were no statistically significant differences between them. Of greater significance was that, with this protocol, the postinstrumentation infection rate was not significantly different whether or not the patient received prophylactic antibiotics.

Comment

Our study and studies previously reported[2, 3] show that the use of prophylactic antibiotics at the time of complex multichannel urodynamic testing does not decrease the postinstrumentation infection rate.

Our 8.1% unsuspected infection rate is similar to that reported by Bergman and McCarthy.[2]

Postinstrumentation infection developed in 10 (18.9%) of the 53 women in the control group, compared with 4 (8.2%) of 49 women who received prophylaxis. Although the 18.9% incidence of postinstrumentation infection is not statistically significant, it is somewhat higher than the previously reported rates of 4%,[2] 10%,[3] and 15%[4] and therefore is clinically important. This higher rate may be attributable to multiple insertions of the catheter during urodynamic study, which increase the chance of creating infection.

The absence of a statistical difference may be because of the relatively small number of patients. Other factors that may affect the results are the dose, duration, and type of prophylactic antibiotic used. Further study of these parameters will be necessary.

There is a high incidence of unsuspected infection before testing and a high incidence of infection after urodynamic testing. To decrease these high rates, perhaps patients should receive prophylactic antibiotic treatment before testing,[2] at least until a study is performed with larger numbers and different antibiotic regimens.

Genetic identification of pregnancies responsible for choriocarcinomas after multiple pregnancies by restriction fragment length polymorphism analysis

**Hisao Osada, MD,[a] Makoto Kawata, MD, PhD,[a] Masao Yamada, PhD,[b]
Ko Okumura, MD, PhD,[c] and Hiroyoshi Takamizawa, MD, PhD[a]**
Chiba and Tokyo, Japan

The pregnancies responsible for two cases of choriocarcinomas were determined by the restriction fragment length polymorphism of human leukocyte antigen–DQ genes in the tumors and leukocytes from the patients, their husbands, and their children. The first case was preceded by three normal pregnancies, and the second case was preceded by two normal pregnancies and a complete hydatidiform mole. Comparison of the restriction fragment length polymorphism patterns revealed that the first case of choriocarcinoma carried the parental genome and originated from the third normal pregnancy, whereas the second case was of androgenetic origin from the complete mole. By choosing an appropriate probe (or probes), restriction fragment length polymorphism analysis is shown to be a useful method for identification of the pregnancy responsible for choriocarcinoma. (AM J OBSTET GYNECOL 1991;165:682-8.)

Key words: Choriocarcinoma, responsible pregnancy, restriction fragment length polymorphism

Choriocarcinoma is a malignant tumor originating from trophoblasts in complete hydatidiform moles, normal, and any other types of pregnancies. If a patient with choriocarcinoma has had multiple antecedent pregnancies, the choriocarcinoma is thought to develop from the last pregnancy on the basis of the interpretation of clinical sequence of these patients. However, the possibility that an earlier pregnancy causes the choriocarcinoma cannot definitely be ruled out. In the case of interrupted postmolar choriocarcinoma, the choriocarcinoma has been proposed to be a legacy from the previous hydatidiform mole rather than from the current nonmolar pregnancy on the basis of the susceptibility of hydatidiform moles to develop choriocarcinoma.[1] Although such proposals remain untested, the accurate identification of the responsible pregnancy is important as a first step toward elucidating the oncogenesis and development of choriocarcinomas.

Genetic studies would determine the responsible pregnancy by proving its identity to choriocarcinoma. The androgenetic origin of complete moles has been demonstrated by chromosomal heteropolymorphism,[2, 3] human leukocyte antigen (HLA) haplotypes,[4, 5] and enzyme polymorphism.[6, 7] In contrast with complete moles, choriocarcinomas often show chromosomal gains, losses, and other abnormalities,[8] and scarcely express HLA antigens[9]; thus further analyses on their chromosomes and HLA haplotypes are difficult. In addition, these genetic markers provide only limited information about a few sites on given chromosomes.

In recent years, many deoxyribonucleic acid (DNA) polymorphisms, which exhibit different lengths of DNA fragments after digestions with certain restriction enzymes (restriction fragment length polymorphisms), have been found in the human genome.[10] On restriction fragment length polymorphism analysis, a highy specific set of alleles at polymorphic loci can identify unrelated persons and also children in a family, except monozygotic twins. Restriction fragment length polymorphism analysis therefore is expected to be a useful and widely applicable method to identify the pregnancy responsible for choriocarcinoma.

By restriction fragment length polymorphism analyses, we determined the responsible pregnancies in two patients with choriocarcinoma preceded by multiple pregnancies; choriocarcinoma developed in one patient after three normal pregnancies, and after two normal pregnancies and a subsequent complete mole in the other patient. Here we show that both choriocarcinomas developed from the last antecedent pregnancies—one from the third normal pregnancy and the other from the complete mole.

6/1/29606

Material and methods

Patients. The first patient had two normal deliveries at the age of 27 and 29 years, but no history of molar pregnancies or abortions. At 31 years old she was delivered of her third child, who weighed 2050 gm at 38 weeks' gestation. Six weeks after the third delivery, she had an emergent hysterectomy indicated by massive uterine bleeding. The tumor mass found in the uterus was histologically proved to be choriocarcinoma. The child is developing normally without elevation of serum human chorionic gonadotropin.

The second patient had two normal deliveries, the first at age 28 years and the second at age 29. The third pregnancy at age 35 was a complete hydatidiform mole. Seven months after termination of the mole, roentgenogram examination showed a metastatic shadow in the chest, accompanied by an elevated level of human chorionic gonadotropin. A hysterectomy was performed and histologic examination confirmed the diagnosis of choriocarcinoma. A part of the surgical specimen was transplanted into nude mice and subsequently produced a developing tumor that was histologically also determined to be choriocarcinoma.

Probes. The restriction fragment length polymorphism probes used in this study were inserts from pDQβ155,[11] an HLA-DQβ cDNA clone; pDQα107,[11] an HLA-DQα cDNA clone; OS-4,[12] a clone containing a sequence assigned to chromosome 18; p4.1H2,[13] a clone containing a sequence assigned to chromosome 19; and pHY10,[14] a clone containing a Y chromosome–specific repeated sequence. These clones were obtained from the Japanese Cancer Research Resources Bank. An insert from a cDNA clone of Leu-2 (CD8),[15, 16] which is a nonpolymorphic single copy gene, was used to standardize the amount of loaded DNA on each lane.

Southern hybridization. DNA was prepared from choriocarcinoma tissue and peripheral blood leukocytes by standard techniques. Each of the DNA samples (7.5 to 10 μg) was digested with an appropriate restriction enzyme, and blotted onto a nylon membrane. The membrane was incubated in prehybridization solution [6× saline solution–sodium phosphate–ethylenediaminetetraacetate (SSPE) buffer, 0.5% sodium dodecyl sulfate (SDS), 2× Denhardt's solution, and 100 μg/ml denatured salmon sperm deoxyribonucleic acid (DNA)] for 2 hours and hybridized with the probes for 16 hours, which had been labeled with phosphorus 32 with a random primer labeling system and mixed at a concentration of 1×10^6 cpm/ml to the prehybridization solution. The membrane was then washed in 2× SSPE, 0.1% SDS, and in 0.2× SSPE, 0.1% SDS for 15 minutes twice each. All procedures were carried out at 65° C. Autoradiography was performed with Kodak XAR-5 film for 1 to 7 days at −70° C with an intensifying screen.

Densitometric analysis. The HLA-DQ restriction fragment length polymorphism bands on the autoradiographs were scanned with a densitometer, and their relative area values were measured with an integrater. The measured band intensity was corrected according to the corresponding intensity of the nonpolymorphic Leu-2 band, which was revealed by the rehybridization of the same membrane with a Leu-2 probe.

Results

Case 1. Genomic DNA isolated from peripheral leukocytes of the patient and the members of her family were digested with PstI, and hybridized with a cDNA probe for an HLA-DQβ chain (chromosome 6). These DNA samples offered several bands, among which four polymorphic bands were numbered from 1 through 4 in order of size (Fig. 1, *A*). The patient had bands 1 and 4, but the husband did not have either of them. All children had one of the bands; thus this segregation pattern indicates that these two bands were independently derived from either of the patient's chromosomes 6. Alternatively, the husband had bands 2 and 3. The first child had both bands, whereas the other two children had only band 3, indicating that band 2 was derived from one of the husband's chromosomes 6, but band 3 from both. These data define the four parental haplotypes: we called them a and b for the patient, and c and d for the husband. Accordingly, the first child had a/c haplotype, the second child had a/d, and the third child had b/d (Fig. 1, *B*).

Genomic DNA simultaneously prepared from the choriocarcinoma tissue offered bands 1, 3 and 4 (Fig. 1, *A*), indicating the three haplotypes a, b, and d. This finding suggests that this tissue contains not only choriocarcinoma cells themselves, but also patient-derived stromal or blood cells. These inevitable components were microscopically observed in the tissue section (data not shown). The absence of band 2 in the tissue excludes the possibility that the choriocarcinoma was derived from the first pregnancy. The possibility of originating from the second or third pregnancies, however, could not be readily determined by the band pattern alone because these later pregnancies showed indistinguishable haplotypes (a/d and b/d) from the choriocarcinoma tissue (a/b/d). To distinguish between them, we measured the intensity of restriction fragment length polymorphism bands with a densitometer.

If the choriocarcinoma had developed from the third pregnancy, band 4 in the tissue would have come from the choriocarcinoma cells and patient-derived cells. The expected intensity value of band 4 of the tissue can be calculated from the measured intensity value of the third pregnancy-derived (but not patient-derived) band 3, and that of the patient-derived band 1 as follows: $10.9 \times (10.0/14.4) + 8.3 \times (3.1/11.1) = 9.8$. This expected value of 9.8 was close to the measured value of 10.1 (Table I). Alternatively, a calculation similar to this excluded the possibility of the second

4	10.9	8.3	10.1 (9.8)†	—	8.3	10.1

*The expected intensity value in the case of the choriocarcinoma being developed from the second pregnancy with participation of the patient's stromal cells. The calculation is 8.9 × (10.0/14.8) + 11.1 × (10.1/8.3) = 19.5.

†The expected intensity value in the case of the choriocarcinoma being developed from the third pregnancy with the participation of the patient's stromal cells. The calculation is 10.9 × (10.0/14.4) + 8.3 × (3.1/11.1) = 9.8.

pregnancy origin in which band 1 in the tissue came from the tumor cells themselves and the patient's cells: 8.9 × (10.0/14.8) + 11.1 × (10.1/8.3) = 19.5. But the corresponding measured value of 3.1 was much lower. Taken together, these results indicate that this choriocarcinoma developed from the third pregnancy, not from either of the earlier pregnancies.

Three other theoretically possible origins, although less likely, need to be considered, including unnoticed early abortions of complete moles, nonmolar pregnancies, and germ cells (a nongestational origin). The first possibility of complete mole origin can be ruled out by a comparison of the restriction fragment length polymorphism band intensities. In this case, the maternal element in the choriocarcinoma tissue is derived only from the patient's stromal or blood cells and thus the intensity ratio of maternal band 1 versus band 4 should be identical between the patient and choriocarcinoma tissue. However, this ratio was 3.1/10.1 = 0.3 in the choriocarcinoma tissue sample, whereas it was 11.1/8.3 = 1.3 in the patient sample (Table I). As for the second possibility of nonmolar origin, if the pregnancy had the same haplotype for chromosome 6 as the third child, then it certainly could not be ruled out, and additional restriction fragment length polymorphism analyses on different chromosomes may be re-

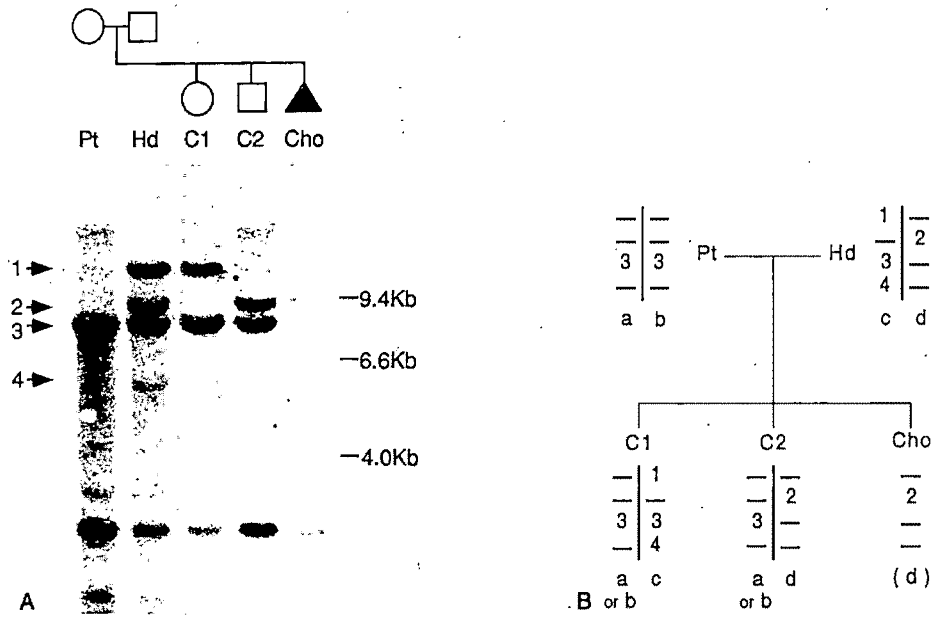

Fig. 2. A, Restriction fragment length polymorphism patterns detected in case 2 by hybridization of *Pst* I–digested DNAs from patient *(Pt)*, husband *(Hd)*, first child *(C1)*, second child *(C2)*, and choriocarcinoma tissue *(Cho)* with HLA-DQα probe. Four informative bands are numbered *1* through *4*, as shown on left of lanes. **B,** Segregation pattern of four parental haplotypes in family of case 2. Numbers *1* through *4* show presence of corresponding bands of **A**, and *hyphen* shows absence. quired for verification. The third possibility of a nongestational origin, which is not a result of any paternal genome, was readily excluded by the presence of the paternally derived band 3 in the choriocarcinoma tissue (Fig. 1, *A*).

Case 2. Genomic DNAs from leukocytes of the patient and the members of her family were digested with *Pst* I and hybridized with a cDNA for an HLA-DQα chain. Four polymorphic bands were numbered from 1 through 4 in order of size (Fig. 2, *A*). These four bands were not present in a liver DNA sample of a nude mouse (data not shown). Only the husband and children had bands 1, 2, and 4 in a segregated pattern, in which the husband had all three bands, the first child had bands 1 and 4, and the second child had band 2. This pattern indicates that bands 1 and 4, and band 2 were derived independently from either of the husband's chromosomes 6. Band 3 was commonly detected in this family, but the intensities of these bands measured with densitometry in the patient and the first child were approximately twice as high as those in the husband and the second child (data not shown). This indicates that band 3 in the patient was derived from both chromosomes 6, but that in the husband was from one, which simultaneously contributed to bands 1 and 4. Thus we could define the parental haplotypes a, b, c, and d (Fig. 2, *B*).

Genomic DNA from the choriocarcinoma tissue that was resected from the patient and subsequently transplanted into nude mice had only band 2, apparently differing from the children. The absence of band 3 in the tissue excludes the possibility of contribution of the patient's genome and cells. Although we could not directly analyze the molar DNA, this choriocarcinoma is most likely to have developed from the complete mole. It should be stressed that the presence of only one husband's haplotype, band 2, in the choriocarcinoma indicates its homozygosity for the chromosome 6.

The homozygosity of this choriocarcinoma was further analyzed with several probes showing restriction fragment length polymorphisms on other chromosomes. The DNA samples were digested with *Taq* I and hybridized with an OS-4 probe for a single-copy gene on chromosome 18 (Fig. 3, *A*). The husband had 8.6 and 6.7 kb bands, whereas the choriocarcinoma had only the 8.6 kb band that was absent in the patient. This result indicates that the choriocarcinoma was androgenetic and also homozygous for chromosome 18.

Similarly, the hybridization of *Sma* I digest with a p4.1H2 probe, which is assigned to chromosome 19, revealed that the husband had 9.0 and 8.0 kb bands, whereas the choriocarcinoma lacked the 9.0 kb band (Fig. 3, *B*). In addition, the hybridization of *Eco*RI digest with a Y-chromosome–specific pHY10 probe resulted in a 3.4 kb band in the husband and second male child, but not in the choriocarcinoma (Fig. 3, *C*). These data are compatible with the homozygosity of this cho-

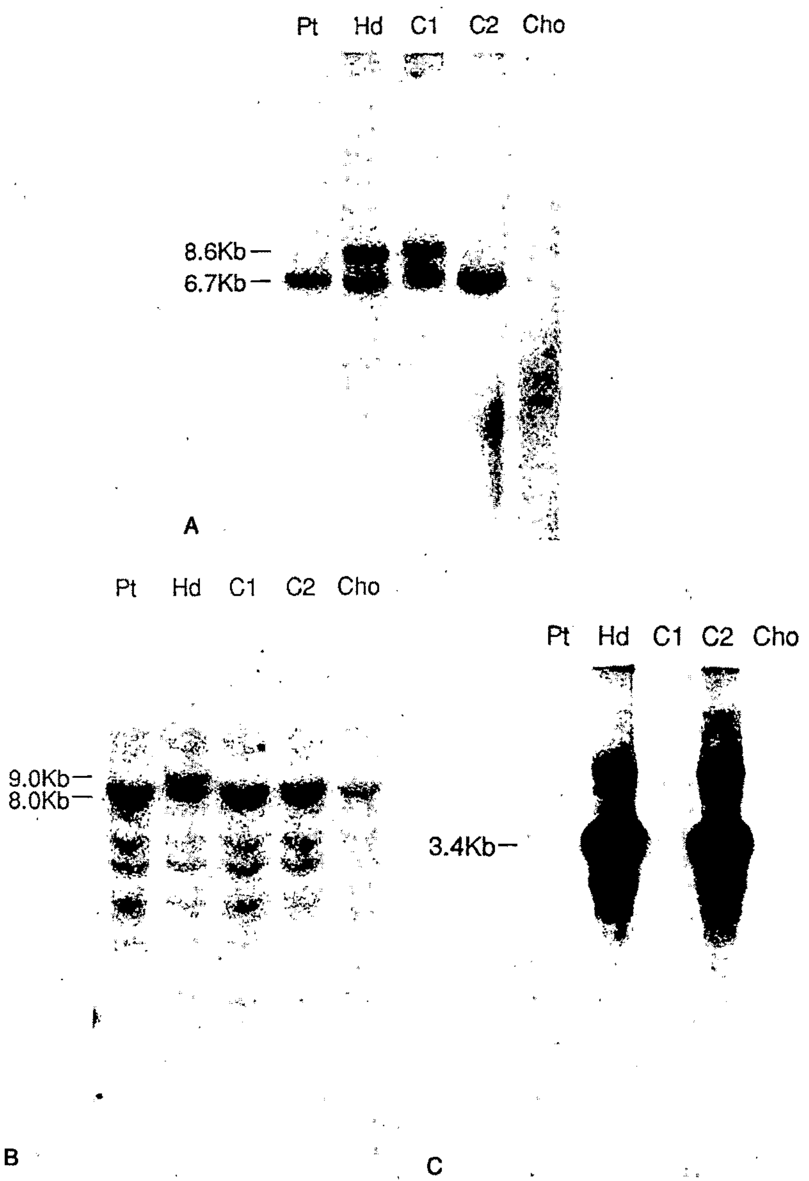

Fig. 3. Restriction fragment length polymorphism patterns detected in case 2 by hybridization of DNAs from patient *(Pt)*, husband *(Hd)*, first child *(C1)*, second child *(C2)*, and choriocarcinoma tissue *(Cho)* with OS-4 **(A)** and p4.1H2 probe **(B)**. Androgenetic origin of choriocarcinoma is shown by restriction fragment length polymorphisms detected with OS-4 probe, whereas homozygous origin is shown by restriction fragment length polymorphisms detected with both OS-4 and p4.1H2 probes. **C,** Southern hybridization of *Eco*RI-digested DNAs from family members in case 2 with Y-chromosome–specific pHY10 probe. Husband and second male child samples show hybridization bands.

riocarcinoma for chromosome 19 and sex because of its androgenetic origin.

No bands were detectable in a nude mouse DNA sample by the hybridization with any of these three probes (data not shown).

Comment

In the first case, a short interval between the third pregnancy and the occurrence of choriocarcinoma empirically suggested that the choriocarcinoma originated from the last pregnancy. Origin from earlier pregnancies, however, remained possible because choriocarcinoma occasionally develops after an extremely long latent interval (e.g., over 10 years, from an antecedent pregnancy).[17] Our restriction fragment length polymorphism analysis, however, directly proved the former assumption. Choriocarcinoma tissue is especially abundant in vascular tracts and blood cells; thus it is likely that this freshly resected choriocarcinoma tissue was contaminated with certain cells of the patient. Densitometric measurements along with careful data analysis could precisely resolve these complicated band patterns from patient-derived cells in our preparation.

In the second case, restriction fragment length polymorphism analysis with HLA-DQα and OS-4 probes showed that the choriocarcinoma was of androgenetic origin. This result indicates therefore that the choriocarcinoma most likely developed from the last complete mole. Because the risk of choriocarcinomas associated with complete moles has been estimated to be between 2000 and 4000 times greater than that of choriocarcinoma with nonmolar pregnancies,[1] the normal pregnancies in this patient were less likely to cause the choriocarcinoma. In this study, we excluded the latter possibility.

A surprisingly high incidence of heterozygosity has been reported in choriocarcinoma arising from postmolar patients by cytogenetic analysis.[18-20] Those results require fundamental reconsideration regarding the direct oncogenic relationship between the choriocarcinoma and complete moles, which mainly (more than 90%) consist of homozygous types. Fisher et al.[21] have reported restriction fragment length polymorphism analysis on two cases of postmolar choriocarcinoma in which one was heterozygous (dispermy) and the other was thought to be homozygous (monospermy). Our androgenetic choriocarcinoma showed homozygosity for three autosomal chromosomes (6, 18, and 19) and a sex chromosome, suggesting that this choriocarcinoma developed from the complete mole of a single sperm origin. These results, however, did not entirely exclude the possibility that the choriocarcinoma is heterozygous for other chromosomes, although 46,XX heterozygous moles, if causal, are very rare (about 2%) in complete moles.

About 1900 DNA clones providing restriction fragment length polymorphism were already reported at the Tenth International Workshop on Human Gene Mapping in 1989.[22] Among them, DNA fragments in the HLA class II region are especially useful for individual identification because they offer multiple informative bands.[23] Indeed, we could distinguish the members of the patients' families by differences in restriction fragment length polymorphism patterns with only one probe for the HLA class II gene. A series of restriction fragment length polymorphisms originated from variable numbers of tandem repeat sequences has also been found on several chromosomes.[24] Thus further restriction fragment length polymorphism analyses with these informative probes that exhibit multiple alleles would facilitate the identification of the pregnancies responsible for choriocarcinomas.

In this study the pregnancies responsible for two choriocarcinomas preceded by multiple pregnancies were successfully determined by restriction fragment length polymorphism analysis. Application of restriction fragment length polymorphism analysis to a broader group of patients would certainly be of benefit to further define the natural history of gestational trophoblastic disease.

Transvaginal fetal echocardiography in early pregnancy: Normative data

Lawrence A. Dolkart, MD, and Faith T. Reimers, RNC, BS, RDMS
Elmira, New York

Fifty-two transvaginal ultrasonographic examinations were performed between 10.0 and 14.9 weeks' gestation for the purpose of documenting normal fetal cardiac anatomy. All standard cardiac projections could be obtained by gestational week 12, and many were imaged by week 11. The four-chamber view was visualized in 90% of fetuses at 12 weeks' gestation and in 100% of fetuses examined at 13 weeks. The aortic root in short axis projection and the left ventricle in long axis view could be imaged in 70% and 40% of fetuses, respectively, by 12 weeks' gestation. Aortic and pulmonary valves were first visualized at 12 weeks, as were five-chamber, ductus arteriosus, and aortic arch views. The mitral and tricuspid valves were resolved in 60% of fetuses by 11 weeks' gestation. This study of normal cardiac anatomy suggests that there may be significant potential for the diagnosis of many fetal cardiac anomalies during the late first and early second trimesters of pregnancy. (AM J OBSTET GYNECOL 1991;165:688-91.)

Key words: Pregnancy, prenatal diagnosis, first trimester, transvaginal ultrasonography, echocardiography

The evaluation of both normal and abnormal fetal anatomy in early pregnancy with transvaginal ultrasonography is under active study. A number of investigators[1-3] have suggested that the prenatal diagnosis of malformations may move into the first trimester because of the ability to resolve small fetal structures with the transvaginal technique. However, before anomalous development can be assessed, the ability to adequately visualize normal anatomy must be examined. The systematic investigation of detailed cardiac anatomy in the first and early second trimesters with this approach has not been described. This study explores the use of transvaginal ultrasonography in visualizing normal early fetal heart anatomy.

Material and methods

Forty-two women at between 10 and 14.9 weeks' gestation were enrolled in this investigation. One patient was excluded because a missed abortion was documented at the time of ultrasonographic examination. Eleven patients were studied twice at two different gestational ages. A total of 52 transvaginal ultrasonographic examinations were available for analysis. All cardiac examinations were videotaped for purposes of documentation and later inspection.

Five gestational age ranges were defined for evaluation, in 1-week intervals from 10.0 to 14.9 weeks (10.0 to 10.9 weeks, 11.0 to 11.9 weeks, etc.). The gestational age at the time of examination was determined in each patient by either a crown-rump measurement or a biparietal diameter measurement with the use of established norms.[4, 5]

Fifteen echocardiographic views of the heart were selected for study because of their known general usefulness.[6, 7] Because at these early gestational ages the resolution of fine detail within the fetal heart might be insufficient to adequately visualize important aspects of

Table I. Criteria required to accept adequate visualization of cardiac views

View	*Criteria*
Four-chamber	Two equally sized ventricles and atria; offset mitral and tricuspid valves; ventricular septum intact up to the cardiac crux
Five-chamber	Two equally sized ventricles and atria; discrete circular aortic cross section in center of heart
Aortic arch	Longitudinal arch view with at least one carotid, brachiocephalic, or subclavian branch clearly arising from the vessel
Short axis aorta	Discrete circular echo representing the aortic root visualized within the center of the heart
Short axis ventricles	Isolated right and left ventricular cavities in cross section with defined interventricular septum
Long axis left ventricle	Defined continuity from interventricular septum through the aortic root in longitudinal (parasagittal) section; mitral leaflet approximated to contralateral aortic wall
Inferior, superior vena cavae	Longitudinal views with vessel entrance into right atrium
Pulmonary trunk	Longitudinal view with definitive connection to right ventricle
Mitral, tricuspid valves	Leaflets as visualized on four-chamber view but interventricular septum not necessarily imaged
Aortic, pulmonary valves	Moving echogenic points near root of vessel in longitudinal or cross-sectional view
Ductus arteriosus	Continuity of pulmonary trunk into descending aorta; no emerging vessels projecting toward neck
Short axis base	Short axis view at level of aortic and pulmonic outflow tracts (pulmonary trunk draping over central aorta in cross section); tricuspid valve and right atrium in view

Table II. Percentage of cardiac structures visualized at each gestational age

View	*10-10.9 wk (n = 8)*	*11-11.9 wk (n = 10)*	*12-12.9 wk (n = 10)*	*13-13.9 wk (n = 13)*	*14-14.9 wk (n = 11)*
Four-chamber	0	30	90	100	100
Five-chamber	0	0	10	54	64
Aortic arch	0	0	20	23	73
Short axis aorta	0	10	70	62	82
Short axis ventricles	0	10	40	31	27
Long axis left ventricle	0	20	40	46	55
Inferior vena cava	0	10	10	54	91
Superior vena cava	0	10	10	23	36
Pulmonary trunk	0	0	40	38	82
Mitral valve	25	60	90	100	100
Tricuspid valve	25	60	90	100	100
Aortic valve	0	0	20	46	64
Pulmonary valve	0	0	20	15	36
Ductus arteriosus	0	0	50	23	73
Short axis base	0	10	30	46	73

anatomy, strict criteria were followed when documenting that a particular cardiac view was indeed imaged. These criteria are described in Table I.

Each ultrasonographic examination took no longer than 10 minutes to perform. An RT 3600 ultrasonography unit (General Electric, Rancho Cordova, Calif.) equipped with a 7.5 MHz transvaginal sector probe was used at double magnification. The study protocol was approved by the hospital's institutional review board for medical research. Written patient consent was obtained in all cases.

Results

Table II itemizes the cardiac views distinguished at each gestational age interval. A complete four-chamber view was consistently obtained by 12 weeks' gestation (in 90% of fetuses). This view was always obtainable by week 13. It was never adequately visualized at 10 weeks' gestation because an intact interventricular septum could not be completely resolved at this early age.

The five-chamber and aortic arch views were not seen in most fetuses until 14 weeks' gestation, although each was imaged in some fetuses by week 12. The resolution of the instrumentation limited consistent identification of the small carotid and subclavian vessels branching from the aorta up toward the neck before 12 weeks' gestation. Definitive identification of the ductus arteriosus in longitudinal view was similarly difficult until 14 weeks' gestation because the origin of tiny neck vessels could not always be established. In contrast, the aorta in short axis was well-defined by 12 weeks' gestation (in 70%), seen as a bright circular echo within the center of the heart. Structural detail was sufficient to relate this cross-sectional aortic view to the pulmonary trunk as a short axis base view in 46% of the fetuses by 13 weeks' gestation.

In 40% of cases a longitudinal (parasagittal) left ventricular view could be imaged by week 12. Earlier than this, the continuity between the aorta and the interventricular septum could not be reliably depicted in most fetuses.

The inferior and superior vena cavae were seen as early as 11 weeks' gestation. The aortic and pulmonary valves were first noted at 12 weeks' gestation, although even at 14 weeks they were not always discovered because of their small size. The complete short axis base view was first imaged at 11 weeks' gestation. The short axis ventricle view was also first visualized at 11 weeks but was inconsistently noted throughout the gestational ages studied.

No structural anomalies were noted in any of the fetuses studied. Because of a history of congenital heart disease or diabetes, eight patients had a formal level II fetal echocardiographic study at 18 to 22 weeks' gestation and in none of these were any cardiac malformations documented. The perinatal outcome of all patients was reviewed. Thirty-eight patients were delivered of infants with no clinical evidence of heart disease. One patient had a spontaneous abortion of unknown cause at 14 weeks' gestation. Another patient had a fetal loss at 22 weeks' gestation because of an incompetent cervix; the fetal heart on autopsy was normal. One patient had a pregnancy termination at 22 weeks' gestation because of bilateral renal agenesis, and an autopsy showed a normal fetal heart.

Comment

Echocardiographic investigation of the fetal heart has become a specialized examination of great importance inasmuch as congenital heart disease remains the most common serious anomaly at birth. The examination is usually performed at about 18 to 22 weeks' gestation. At this time the traditional transabdominal approach has sufficient resolution to delineate the small details of human heart anatomy. Earlier confirmation of normal cardiac anatomy is desirable to allay the anxiety of patients with a family history of congenital heart disease or to offer the option of early pregnancy termination or close follow-up should a cardiac anomaly be documented.

With the advent of high resolution transvaginal ultrasonography there is increasing interest in the analysis of normal and abnormal fetal anatomy during the first and early second trimesters of pregnancy.[1-3] Timor-Tritsch et al.[8] described a variety of fetal anatomic features detectable in 38 patients scanned with a 6.5 MHz transvaginal probe. They identified and described head, skeletal, and facial anatomy during the first trimester but structural cardiac details were not discussed in their survey. Kushnir et al.[9] studied first-trimester fetal cranial anatomy in 50 women by means of the transvaginal approach. They visualized many intracranial structures traditionally imaged only in the second trimester by the transabdominal route. Guzman[10] has reported the detection of gastroschisis at 12 weeks' gestation in an obese patient who was otherwise difficult to examine transabdominally. Cullen et al.[3] reported 33 fetuses between 9 and 13 weeks' gestation with structural anomalies, none of which were cardiac in nature. They suggested that with transvaginal ultrasonography, prenatal diagnosis of fetal anomalies would shift into the first trimester.

The only published report of diagnostic transvaginal fetal echocardiography to date is that of Gembruch et al.[11] They used a 5 MHz transvaginal probe to diagnose a complete atrioventricular canal defect and complete heart block at 11 weeks' gestation and subsequently performed an elective abortion on the basis of this information. They presented unpublished data suggesting that a four-chamber view was obtainable in 10 of 10 fetuses at 12 weeks' gestation and in 8 of 10 fetuses at 11 weeks' gestation. Our findings are generally supportive of their data, although with the use of strict criteria for the four-chamber view we could not image this projection in every fetus until 13 weeks' gestation. Echo dropout artifact obscuring the interventricular septum was invariably the reason for failure to visualize the complete four-chamber view at 10 to 12 weeks' gestation. Still, 90% of fetuses had a well-documented four-chamber view by 12 weeks. In contrast with this finding, Catanzarite and Quirk[12] could only establish an optimal four-chamber view on transabdominal examination in <20% of fetuses at 13 to 14 weeks' gestation. The importance of a normal four-chamber view has been emphasized by Copel et al.,[13] who showed that if this view on transabdominal ultrasonographic study was normal, >90% of congenital heart anomalies could be ruled out. Our data suggest that screening for congenital heart disease with the four-chamber view might be started as early as 12 to 13 weeks' gestation with the transvaginal approach.

It would appear that the earliest defined cardiac structures visible in the first trimester are the mitral and tricuspid valves. These are highly echogenic by week 10 to 11 and their range of motion is greater than any other intracardiac component. Fetal heart motion noted before 10 weeks' gestation most likely represents the movement of these two valves. Our data show that each atrioventricular valve can be individually resolved by 10 weeks' gestation in 25% of cases, and their normal offset position (tricuspid more apical than mitral) can be defined at this time. It was noted that these valves are usually observed before the interventricular septum can be identified.

Especially prominent by week 12 is the short-axis view of the aortic root, noted in 70% of fetuses at this age. The pulmonary trunk and the long parasagittal left ventricular view can also be seen in many cases by 12 weeks' gestation. These views in conjunction with the four-chamber projection, if normal in appearance, have the potential to rule out most structural defects by the third month of pregnancy.

This study illustrates the great quantity of fetal cardiac information available with the use of transvaginal ultrasonography in early pregnancy. However, some caveats concerning early cardiac diagnosis must be cited. Certain planes of view may be limited by the fixed linear axis of the ultrasonographic probe during the transvaginal examination, and fetal position often dictates the views that can be imaged. There is no information yet available concerning the sensitivity, specificity, and predictive value of first-trimester ultrasonographic cardiac diagnosis. Furthermore, considerable experience with second-trimester fetal echocardiography is necessary before attempting first-trimester diagnosis because magnification and resolution are limited in early pregnancy via the transvaginal route. Echo dropout artifact of small intracardiac structures (e.g., the interventricular septum in early four-chamber views) may lead to erroneous diagnosis of cardiac disease, so appropriate confirmation of a structural anomaly might necessitate serial ultrasonographic examinations. Some structural cardiac defects, such as aortic or pulmonic stenosis and corrected transposition of the great arteries, are exceedingly difficult or impossible to detect even with late second-trimester diagnosis.[14] These malformations will also not be amenable to first-trimester diagnosis. This study has documented that virtually all standard cardiac views can be visualized with the transvaginal approach by 13 weeks' gestation, and many can be obtained as early as 11 weeks. On the basis of these observations of normal cardiac anatomy it would appear that late first-trimester and early second-trimester diagnosis of congenital heart disease should be possible.

Effects of angiotensin II on atrial natriuretic peptide in pregnancy

Marion A.L. Didden, MD,[a] Marcel P. Hoekstra, MD,[a] Jos H.A. Vollebergh, MD,[a] Andries Schellekens, PhD,[b] and Pieter A. de Jong, PhD[a]
Eindhoven, The Netherlands

To clarify the effects on angiotensin II and blood pressure on plasma atrial natriuretic peptide in pregnancy, angiotensin II was infused in 37 healthy, normotensive pregnant women in week 32 of gestation. Levels of atrial natriuretic peptide were determined with the women in a sitting position 3 days before the test and in the left lateral recumbent position immediately before and after the test. Levels of atrial natriuretic peptide were not influenced by parity or salt intake. They were found to be significantly higher in the left lateral recumbent position than in the sitting position. There was also a significant increase in atrial natriuretic peptide levels during angiotensin II infusion. A dose of angiotensin II <1.5 ng/kg/min did not affect atrial natriuretic peptide levels. Rise in atrial natriuretic peptide levels was minimally correlated with rise in mean arterial pressure, as caused by acute vasoconstriction from angiotensin II infusion. Therefore it is suggested that, in pregnancy, the response of atrial natriuretic peptide to angiotensin II is mediated not only by changes in blood pressure but also by angiotensinergic receptor activity in the atria. (AM J OBSTET GYNECOL 1991;165:692-5.)

Key words: Pregnancy, human; atrial natriuretic peptide; angiotensin II infusion

Atrial natriuretic peptide is a hormone with potent natriuretic and diuretic effects in man. The release of atrial natriuretic peptide by the heart is stimulated when pressure in the right or left atrium is raised.[1-3] Atrial natriuretic peptide is thought to respond primarily to increases in central blood volume,[4] acting in a homeostatic fashion to return central blood volume to normal and decrease blood pressure. Notwithstanding vast changes in the plasma volume and cardiac output in pregnancy, no (conclusive) evidence of a significant rise in atrial natriuretic peptide in normotensive pregnancies has been published. In preeclampsia, plasma volume and right atrial pressure are lower than in normal pregnancies.[5,6] The paradox, however, is that in preeclampsia the atrial natriuretic peptide concentration (notwithstanding its natriuretic and diuretic power) is higher than in normal pregnancy.[7]

In support of the hypothesis that high atrial natriuretic peptide levels are secondary to elevated angiotensin II levels, pressor infusions of angiotensin II have been found to raise plasma atrial natriuretic peptide levels both in nonpregnant subjects[8,9] and in pregnant ones.[10] Other investigators did not confirm this influence of angiotensin II infusions on atrial natriuretic peptide levels in plasma.[11] It seems that central blood volume and plasma angiotensin II can independently affect atrial natriuretic peptide levels.[12]

In pregnancy the angiotensin II pressure test is a good predictor of a forthcoming pregnancy-induced hypertension.[13-16] Regarding atrial natriuretic peptide, the response to angiotensin II may be mediated by changes in blood pressure levels, increased angiotensin receptor activity in the atria, or both.[9] To elucidate this point during pregnancy, the effects of subpressor and pressor infusions of angiotensin II on plasma atrial natriuretic peptide were investigated.

Patients and methods

Thirty-seven women, all participating in the "Salt restriction in pregnancy" project, gave informed consent to the study protocol, which was approved by the hospital's ethical committee. They were women with an ultrasonography-dated, singleton pregnancy, a mean age of 29.75 years (22.95 to 36.64) and a mean weight of 74.0 kg (52.3-111.4).

None of the nulliparous women ($n = 22$) had a history of renal disease or a personal history of hypertension, whereas all of the parous women ($n = 15$) had a personal history of pregnancy-induced hypertension, preeclampsia, stillbirth, or abruptio placentae. In the first trimester of pregnancy all patients were divided at random into one group with a free-choice diet and another one that followed a strongly sodium-restricted

diet. The diet was considered strongly sodium restricted if sodium excretion in several 24-hour urine samples throughout pregnancy was consistently <30 mmol/24 hr. The diet was considered not sodium restricted if sodium excretion in 24-hour urine samples exceeded 60 mmol/24 hr. If sodium excretion in the 24-hour urine samples was >30 but <60 mmol/24 hr, the diet was considered intermediately sodium restricted (Table I).

In week 32 of gestation, up to 3 days before the angiotensin II infusion, venous blood samples were collected for atrial natriuretic peptide determination from 26 of the total population of 37 normotensive (diastolic blood pressure <85 mm Hg) pregnant women while they were in a sitting position. The fully standardized angiotensin II infusion test of Gant et al.[13] was modified as follows: The patient was placed in the left lateral recumbent position with an intravenous line in the right arm. A 5% dextrose solution was administered by drip. The intravenous system could be switched to another 5% dextrose solution containing angiotensin II (Hypertensin, Ciba-Geigy Ltd., Basel) in a concentration of 1 μg/ml. The rate of infusion of the angiotensin II solution was regulated by an infusion pump.

When a steady state in blood pressure levels (with an automatic recorder [Dinamap vital signs monitor model 1846, Critikon Inc., Tampa] on the left arm) was reached, venous blood samples were collected for atrial natriuretic peptide determination just before and after the angiotensin II infusion.

The angiotensin II solution was started at a rate of 3 ng/kg/min after a constant diastolic blood pressure had been measured during a period of at least 15 minutes; the rate of infusion was raised every 4 minutes by 1 ng/kg/min. The test was considered positive if the effective pressure dose (the dose of angiotensin II required to elevate baseline diastolic blood pressure 20 mm Hg) was <12 ng/kg/min. Angiotensin II administration was stopped when the diastolic blood pressure had risen 20 mm Hg or the dose of angiotensin II had reached 12 ng/kg/min, although Gant et al. continued infusion at higher doses until the effective pressor dose was reached.

Four of the 37 normotensive pregnant women received a sub-subpressor infusion of angiotensin II (1.2 ng/kg/min). A subpressor infusion of angiotensin II (12 ng/kg/min) was given to 28 women, increasing diastolic blood pressure from −5 to 19 mm Hg. Pressor infusions of angiotensin II (<12 ng/kg/min) were given to five women, increasing diastolic blood pressure 20 mm Hg. All tests were performed in the morning to avoid the influence of diurnal variations of plasma levels of endogenous angiotensin II and atrial natriuretic peptide.[17] For the same reason the blood sample up to 3 days before the test was collected in the morning. Plasma immunoreactive atrial natriuretic peptide was measured by radioimmunoassy as previously described.[18] Blood was collected in chilled polystyrene tubes containing potassium and ethylenediaminetetraacetic acid (1.5 mg/ml blood) and aprotinin (Trasylol, 200 kIU/ml blood). Blood was kept on ice and centrifuged (4° C) as soon as possible. Plasma was divided in portions and stored at −80° C. Before the assay, plasma was extracted on SepPak C18 reverse phase columns (Waters Associates, Milford, Mass). The antibody in the radioimmunoassay was elicited against α-human atrial natriuretic peptide (1-28) in sheep; the tracer hormone was iodine 125–monoiodotyrosyl–human atrial natriuretic peptide (1-28), purified by means of aqueous phase liquid chromatography. The separation of bound and free hormone was performed by horse second antibody against sheep, coupled to solid-phase radioimmunoassay. The recovery of human atrial natriuretic peptide (1-28) that was added to plasma was 90% ± 5%. The sensitivity was 0.8 pg per tube (8 pg/ml plasma). The interassay and intraassay precisions were 12% and 9% respectively. Statistical analyses were performed with the Wilcoxon signed rank test and the Mann-Whitney test. Levels of significance were $p < 0.05$. Results were expressed as median and range. Presence or absence of increase was determined by the sign test, and correlation coefficients were calculated.

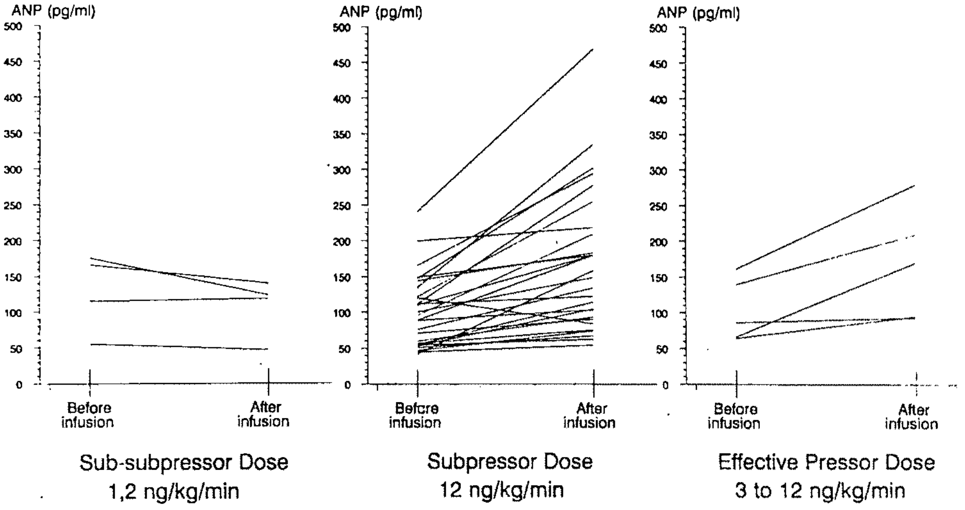
Table I. Number of nulliparous and parous patients according to dietary sodium restriction.

	Nulliparous	*Parous*	*Total*
Sodium restricted (<30 mmol/24 hr)	1	8	9
Intermediate sodium restricted (30-60 mmol/24 hr)	0	1	1
Not sodium restricted (>60 mmol/24 hr)	21	6	27
TOTAL	22	15	37

Results

All normotensive women had lower atrial natriuretic peptide levels while they were in a sitting position than just before the start of the angiotensin II infusion while they were in left recumbent position (sitting, 50.5 pg/ml, range 27 to 86; before test, 100 pg/ml, range 42 to 240; $p < 0.0001$). There were no differences between nulliparous and parous women or between sodium restricted and free-choice diets.

Fig. 1 shows that 45 minutes of sub-subpressor angiotensin II infusion (1.2 ng/kg/min) in the four normotensive pregnant women did not increase atrial natriuretic peptide levels (before test, 139.5 pg/ml, range



Sub-subpressor Dose
1,2 ng/kg/min

Subpressor Dose
12 ng/kg/min

Effective Pressor Dose
3 to 12 ng/kg/min

Fig. 1. Atrial natriuretic peptide before and after infusion of sub-subpressor dose (1.2 ng/kg/min), ubpressor dose (12 ng/kg/min), or effective pressor dose (3 to 12 ng/kg/min and rise in diastolic blood pressure of ≥20 mm Hg) of angiotensin II.

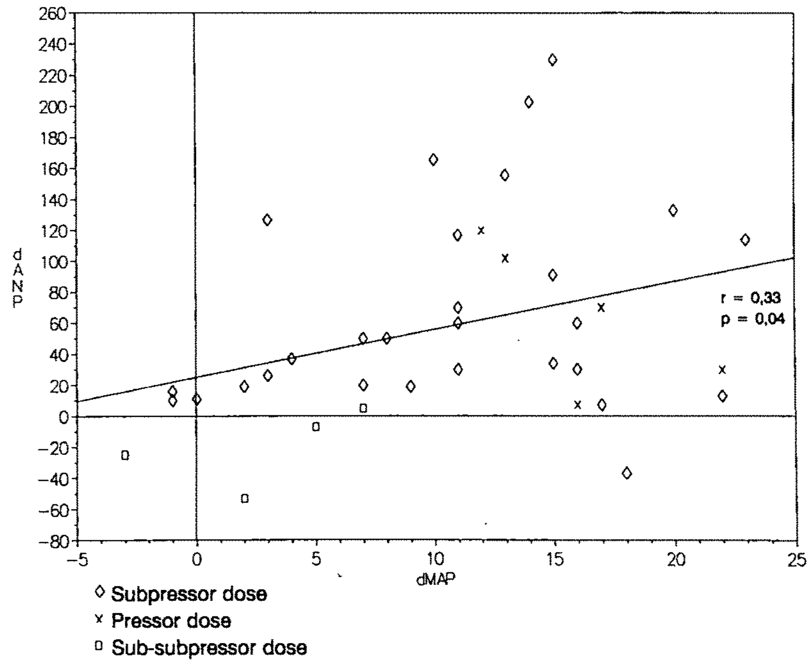


Fig. 2. Relationship between change in mean arterial pressure (*dMAP*, millimeters of mercury) and change in plasma atrial natriuretic peptide (*dANP*, picograms per milliliter) during angiotensin II infusion for sub-subpressor dose (□), subpressor dose (◇), and effective pressor dose (×).

54 to 175; after test, 120.5 pg/ml, range 47 to 140). However, subpressor infusions of angiotensin II at a maximum level of 12 ng/kg/min in 28 women significantly increased atrial natriuretic peptide levels (before test, 98 pg/ml, range 42 to 240; after test, 154.5 pg/ml, range 55 to 470; $p < 0.0001$). After angiotensin II pressor infusion (4 to 12 ng/kg/ml) the atrial natriuretic peptide levels rose significantly, from 85 pg/ml (range 64 to 160) to 170 pg/ml (range 92 to 280) ($p < 0.05$). In spite of a tendency toward a correlation between an increase in mean arterial pressure and an increase in atrial natriuretic peptide levels during angiotensin II infusions, this tendency did not reach statistical significance ($r = 0.33$; $p = 0.04$) (Fig. 2).

Comment

The role of atrial natriuretic peptide in blood pressure regulation and the role of blood pressure in atrial natriuretic peptide regulation in pregnancy is not yet fully understood. The release of atrial natriuretic peptide may be controlled by a number of mechanisms, such as enhanced receptor-mediated responses that are caused by known vasoconstrictor agents such as angiotensin II and a rising pressure in the atria. A trivial activity like a change from sitting to recumbent position causes a higher atrial pressure and a higher atrial natriuretic peptide level.[19, 20] In accordance with this, the atrial natriuretic peptide levels increased significantly when the normotensive pregnant women were lying in a left lateral position.

It should not be surprising that, during pregnancy, the atrial natriuretic peptide levels are significantly elevated by pressor angiotensin II infusions. The test of Gant et al. is based on an increase in diastolic blood pressure by 20 mm Hg. So the resulting acute vasoconstriction of the arteriolae will affect, in one way or the other, the atrial stretching and thus the atrial natriuretic peptide levels. In the nonpregnant situation a close relationship between a change in mean arterial pressure and a change in plasma atrial natriuretic peptide during angiotensin II infusions has been established.[9]

However, in this study elevated atrial natriuretic peptide levels were found not only during pressor angiotensin II infusions but also during subpressor angiotensin II infusions. Moreover, the close correlation between a change in mean arterial pressure and a change in plasma atrial natriuretic peptide during angiotensin II infusions seems to have vanished in pregnancy.

The study design itself could elevate the atrial natriuretic peptide levels, but a lack of change in atrial natriuretic peptide during the sub-subpressor angiotensin II infusions in this study is contradictory to that idea. The results of this study lead to the hypothesis that during pregnancy the response of atrial natriuretic peptide to angiotensin II may be mediated by changes in blood pressure, as well as by angiotensinergic receptor activity in the atria.

We thank Mr. Ernst Bruynis for his accurate work in determining atrial natriuretic peptide and Mr. Frans J. H. C. Driessen for valuable help with the manuscript.

Expression of cytokine receptors and markers of differentiation in human papillomavirus–infected cervical tissues

Minneapolis, Minnesota

Human papillomavirus infection of the uterine cervix is associated with a spectrum of benign, premalignant, and malignant epithelial lesions, a process that appears to require the coordinated effects of secondary cellular and environmental events. We have used flow cytometry and immunohistochemistry to examine the expression of the cellular markers for proliferation (interleukin-1, epidermal growth factor receptor, and transferrin receptor) and the markers of cellular differentiation (filaggrin and low-molecular-weight cytokeratin) in normal and human papillomavirus–infected human cervical tissues representing the natural range of human papillomavirus–induced disease. The results were correlated with the histologic grade of disease, human papillomavirus type, cellular deoxyribonucleic acid content, and cell cycle status. Interleukin-1 and transferrin receptor were slightly increased in high-grade dysplasias and in squamous cell carcinomas. Filaggrin expression was found to be inversely related and cytokeratin and epidermal growth factor receptor expression directly related to the degree of neoplasia. These findings indicate that cytokeratin and epidermal growth factor receptor are useful markers of cell proliferation in human papillomavirus–infected tissues and that their expression may directly increase as a result of infection. (AM J OBSTET GYNECOL 1991;165:696-705.)

Key words: Human papillomavirus deoxyribonucleic acid, growth factors, cellular differentiation, flow cytometry

Human papillomavirus (HPV) infection of the uterine cervix is associated with the development of a spectrum of benign and malignant epithelial lesions, on the basis of the fact that viral deoxyribonucleic acid (DNA) is detected in these lesions in the majority of cases.[1] Although the epidemiologic data support a role for HPV in the development of cervical neoplasia, it is generally regarded that HPV is not a sole causative agent but rather may be an initiating event in what is considered to be a multistep process of neoplastic transformation.[2]

A continuum of morphologic changes occurs in cervical tissue infected with HPV that is marked by the gradual increase in cellular dysplasia, increased mitotic activity, microinvasiveness, and loss of specific viral cytopathic features such as koilocytosis and viral capsid antigens.[3] There are also a host of biochemical alterations at the nuclear, cytoplasmic, and plasma membrane level that also take place. The expression of cytoskeletal proteins such as cytokeratin and of differentiation-dependent cytoplasmic proteins such as filaggrin and involucrin are markedly altered in cells containing HPV DNA.[4,5] These markers can be used to characterize the neoplastic state. However, quantification is not possible on the basis of current methods. As we show below, flow cytometric analysis permits accurate and sensitive quantification of these parameters.

Similar methods can be used to determine the proliferative activity of cells containing HPV DNA. There are more than 50 subtypes of HPV, yet only a few such as HPV types 16, 18, and 31 DNAs are consistently found in malignant tumors, whereas several nononcogenic viral types such as HPV types 6 and 11 were usually, but not exclusively, associated with benign lesions.[6] The nature of the differences between these viruses in their ability to impart cellular transformation is unknown but is purported to be due to variations in their genomic organization, levels of viral gene transcription, and functional activity of the virus-derived oncoproteins.[7] The physical state of the viral DNA within cells, whether episomal or integrated into the host chromosomes, has been shown to be an important predictor of malignant progression.[8] HPV by itself, however, does not appear to be able to induce cellular transformation. In vitro studies examining the capacity of HPV DNA to transform primary cells in culture illustrate that HPV must act in concert with secondary

cellular or host factors, such as the activated oncogenes Ha-*ras* to achieve the fully transformed phenotype.[9]

A number of factors intrinsic to the host may contribute to the process of cervical tumorigenesis, including extracellular factors such as steroid hormones or the integrity of the immune system.[10, 11] In addition, several studies have examined the role of cellular cytokines in cellular transformation in non-HPV-infected cells, demonstrating in particular how certain growth factors and their receptors may function as tumor promotors and enhance the process of cell transformation. The expression of growth factor receptors has been shown to be clinically important in the assessment of tumors in patients and appears in some cases to portend prognostic significance.[12] Recently, there has been evidence to suggest that an increased expression of transferrin or epidermal growth factor receptors is linked to progression of HPV disease.[13] In vitro studies corroborate these results, showing that immortalized cell lines containing HPV type 16 DNA have an altered responsiveness to growth factors such as estrogen, progesterone, and epidermal growth factor.[14] This study was designed to examine the role of several cytokines such as cytoplasmic interleukin-1 (IL-1) and cytokine receptors for epidermal growth factor and transferrin in a series of HPV-associated cervical lesions, by determining whether the expression of these markers correlates with the presence of HPV DNA, the level of cellular differentiation, DNA ploidy, cell cycle analysis, and histopathologic features.

Material and methods

Tissue collection. Samples of cervical cells were obtained from a series of women visiting a local medical center. The cervix of each patient was swabbed with 3% acetic acid and visualized with a colposcope. Sampling was performed by a gynecologic oncologist (L.F.C.) with a Cytobrush (International Cytobrush, Inc., Hollywood, Fla.) directed to areas suspicious for HPV infection, followed by a biopsy with 3 mm biopsy forceps. The exfoliated cell samples were transported in cold RPMI 1640 media (Gibco, BRL, Gaithersburg, Md.) containing penicillin (200 U/ml), streptomycin (200 U/ml), and amphotericin B (Fungizone) (5 μg/ml) and refrigerated. The portion of the samples used for flow cytometry was processed within 3 hours of collection, first by centrifugation to pellet the cells, then by repeated washings with 10 ml of cold phosphate-buffered saline solution. The samples were resuspended in 5 ml phosphate-buffered saline solution and treated with type II collagenase and Dispase (Boehringer-Mannheim, Indianapolis) at a final concentration of 10 mg/ml and incubated at 37° C for 30 minutes. The samples were further disaggregated with gentle pipetting, resulting in a uniform cell suspension. Cell viability was routinely 85% to 90%. The biopsy samples were frozen in liquid nitrogen and later routinely processed after formalin fixation and paraffin embedding.

DNA analysis by Southern blot. A portion of the exfoliated cervical cells was extracted for total cellular DNA by pronase treatment, phenol extraction, and ethanol precipitation, as described previously.[6] Total cellular DNA from each sample (5 μg) was digested with the restriction enzyme *Bam*HI, and subjected to one-dimensional gel electrophoresis as previously described.[6] Electrophoresed cellular DNA was denatured in alkali, neutralized, and transferred to a nylon membrane (Zeta-bind, BRL, Boston). Filters were prehybridized and hybridized as previously described, probed with 5 ng/ml random-primed HPV plasmid DNA (specific activity, 4 to 6 × 10^8 cpm/μg), and washed under very-high-stringency conditions (−4° C), which can differentiate HPV type 6 from HPV type 11.[6, 15] Damp filters were autoradiographed with Kodak XAR-5 x-ray film (Eastman Kodak, Rochester, N.Y.) and intensifying screens at −70° C. HPV types 6, 11, 16, and 18 plasmid DNAs were a generous gift from Drs. L. Gissmann and H. zur Hausen, HPV type 31 was from Dr. A. Lorenz, and HPV type 33 from Dr. G. Orth.

Flow cytometric analysis. Disaggregation and preparation of a uniform suspension of ectocervical cells were performed as described previously.[16] Samples were stained for surface and cytoplasmic markers and for total cellular DNA, by means of a modification of a procedure described previously.[17] Briefly, samples were washed twice with cold phosphate-buffered saline solution and resuspended in cold phosphate-buffered saline solution. Totals of 1 to 2 million cells were aliquoted for each staining reaction, which was performed in sterile tubes in a final volume of 120 μl. Unfixed cells were stained with the monoclonal antibodies for transferrin receptor (Becton-Dickinson, Mountain View, Calif.), or epidermal growth factor receptor (Bioscience Products Inc., Indianapolis). Aliquots of cells fixed in cold 50% ethanol were stained with the markers filaggrin (Biomedical Technologies Inc., Stoughton, Mass.), cytokeratin (clone CAM 5.2) (Becton-Dickinson), and IL-1 (Olympus Immunochemicals, Lake Success, N.Y.). All primary antibodies were monoclonal murine antihuman reagents commercially labeled with either fluorescein isothiocyanate or phycoerythrin. Antibodies were incubated with cells at room temperature for 40 minutes, followed by two washes with phosphate-buffered saline solution. Samples and normal peripheral blood lymphocytes were stained for each of the respective markers and then compared with samples with nonspecific staining by fluorochrome-labeled IgG1 murine sera (Becton-Dickinson). In an effort to minimize the detection of intermixed cells and cellular fragments, the measurement of mean fluorescence of these markers was standardized by electronically selecting (gating) only those cells with mean cell diameter > 20 μm. Propidium iodide staining for total cellular DNA content was performed on ethanol-fixed cells as previously described.[16, 17] Analyses were performed on a Becton-Dickinson FACS 440 flow cytometer with a 10 mW helium-neon laser.

Histopathology and immunohistochemistry. Standard sections were stained with hematoxylin and eosin; the histologic diagnoses were reviewed by the authors (R.C.M. and M.J.S.) and corroborated by an independent pathologist. The diagnoses were classified according to standard nomenclature for grading cervical dysplasia, as initially proposed by Richart.[18] Each sample was subsequently stained with the markers used for flow cytometry according to methods of immunohistochemistry as previously described.[19] Primary antibodies were applied dropwise to deparaffinized tissue sections to a final dilution of 1000 : 1 to 2000 : 1 and incubated overnight at 4° C. The secondary biotin-conjugated horse antimurine antibody was incubated for 1 hour at room temperature. Appropriate positive control tissues were prepared with each staining procedure.

Results

Patient samples and detection of HPV DNA by Southern blot. Thirty-four women who were seen at the Gynecology Clinic of Hennepin County Medical Center in Minneapolis were included in this study. Biopsy and cervical scrape samples of the uterine cervix were analyzed for the expression of cellular markers of proliferation and differentiation by flow cytometry. These data were correlated to the histologic diagnosis and results of Southern blot analysis to detect viral DNA. Efforts were made to select patients whose diagnoses covered a broad range of clinical manifestations of HPV-associated cervical diseases, ranging from normal to severe dysplasia and squamous carcinoma (Table I). In this table and in subsequent figures, samples were grouped according to their histologic criteria and, while shown together, were not intended to represent a biologic continuum.

HPV infection of the cervix was determined by detection of HPV type-specific DNA by Southern analysis. Fig. 1 illustrates the serial hybridizations of filters with radiolabeled HVP DNA. A positive sample was identified as an 8 kb fragment, which is the unit length of the HPV genomes. Although many more types of HPV are known to exist in the cervix, the ones examined represent the types most frequently detected in anogenital lesions. In several samples (e.g., cases 11, 19, 24, 26, 29, and 32) bands other than 8 kb were observed, indicating integration events or deletion mutants of episomal DNA.

The correlation of histologic appearance of cervical samples with the detection of HPV DNA is listed in Table I. Overall, 24 of 34 patient samples were HPV DNA positive. No HPV DNA was detected in the eight biopsy samples with normal or nonspecific histologic types. In contrast, five of eight samples showing features of condyloma acuminatum or low-grade dysplasia were positive for HPV type 6 or 11, one case for HPV type 16, and two cases were HPV DNA negative. HPV DNA was detected in all 16 cases of moderate or high-grade dysplasia. HPV type 16 DNA was detected in 10 patient samples; one case of grade 1 cervical intraepithelial neoplasia, seven cases of grades 2 and 3 cervical intraepithelial neoplasia, and two invasive squamous cell carcinomas. HPV type 18 DNA was detected in six cases of grade 2 and 3 lesions. HPV type 31 DNA is infrequently detected in cervical dysplasias but was seen in three grade 3 cervical intraepithelial neoplasia lesions. No cases demonstrated hybridization with multiple HPV types.

DNA ploidy analysis of cervical cells stained with propidium iodide. Neoplastic transformation is associated with aneuploid populations of tumor cells in most de novo malignancies, a feature that can be detected and characterized by flow cytometry on cell samples stained for total cellular DNA.[20] In addition, DNA aneuploidy has been shown to correlate with higher-grade histologic diagnosis, the expression of cell proliferation antigens, and the loss of expression of papillomavirus capsid antigen; therefore it was examined in this study.[21]

DNA ploidy of the patient samples and normal peripheral blood lymphocytes was analyzed by flow cytometry after samples of fixed cells were stained with propidium iodide; the results are provided in Table II. The coefficient of variation, a measure of precision, was low for all samples and ranged between 3.2% and 7.0%. Five of the 34 cervical samples analyzed contained hyperdiploid G_1/G_0 populations of cells, which were distinct from the larger diploid population. One case of grade 1 cervical intraepithelial neoplasia, two of grade 3 cervical intraepithelial neoplasia, and two of squamous cell carcinoma were found to be aneuploid, and each was positive for HPV DNA (Table II). Similarly, the DNA index, calculated as the ratio of the size and fluroescence of the hyperdiploid peak to the diploid peak of the reference cells (peripheral blood lymphocytes), ranged between 1.6 and 1.88 for the aneuploid samples.

The proliferative index is the percentage of cells in the $S + G_2/M$ phase and was calculated from samples stained for total cellular DNA. Samples of normal cer-

Genomic DNA (5 μg) from samples of cervical cells was extracted and digested with the restriction endonuclease *Bam*HI and then electrophoresed. The DNA was transferred to nylon membranes by the Southern blot method. Hybridization was performed with cloned HPV types 6, 11, 16, 18, and 31 under very-high-stringency conditions

vical epithelium had a mean proliferative index of 16%, which compares with the proliferative index of peripheral blood lymphocyte cells (15.5%) and increased to 26% in the grade 3 cervical intraepithelial neoplasia group. Samples in the grade 1 cervical intraepithelial neoplasia group had a slightly lower proliferative index (15%), which is not statistically significant from that of the normal samples ($p > 0.1$). There was also a positive correlation between the presence of HPV DNA as determined by Southern blot and an increased proliferative index ($p < 0.05$); this relationship was also found to hold for the group of samples containing the oncogenic HPV types 16, 18, and 31.

Markers of differentiation with histologic grade of dysplasia and HPV types. Infection of cervical tissues with HPV has been shown to alter the pattern of differentiation of squamous epithelium. Concomitant with this is altered expression of differentiation-dependent proteins, such as the cytokeratin family of intermediate filaments and filaggrin, a precursor to keratohyaline granules. A series of monoclonal antibodies have been developed for the identification of cytokeratins of varying molecular weights. Low-molecular-weight species of cytokeratin have been found in undifferentiated and malignant epithelium, in particular, squamous cell carcinoma.[4] In this study we have used the monoclonal antibody CAM 5.2 to detect the low-molecular-weight cytokeratin protein, to identify undifferentiated or

neoplastic exocervical cells. The cytoplasmic protein filaggrin is synthesized by normal squamous cells and normally sequestered in the superficial layers of squamous epithelium; in this study it was used as a marker of normal keratinocytic differentiation.[5]

Ethanol-fixed cells from cervical brushings of patients were stained for these markers of differentiation and measured by flow cytometry and correlated with their histologic grade and HPV type. Fig. 2 illustrates the relationship between the average expression of these two markers for the aggregate of patient samples showing various histologic groups of HPV-associated cervical lesions that we have studied. Cytokeratin was differentially expressed in normal and neoplastic tissue. Normal and grade 1 and 2 cervical intraepithelial neoplasia samples had measurable expressions of cytokeratin that were not significantly different from each other ($p > 0.1$). Both cases of condyloma acuminatum demonstrated slightly less bright staining for cytokeratin. By contrast, grade 3 samples were on average nearly twofold brighter than the lower-grade sample groups, which was not statistically significant ($p > 0.1$), but consisted of a single population of large cells (mean cell diameter, 20 μm). Both cases of squamous cell carcinoma strongly expressed cytokeratin that was twofold greater than that of the grade 3 cervical intraepithelial neoplasia samples ($p < 0.01$). The expression of cytokeratin was also analyzed in a series of cervical carcinoma cell lines that contain HPV DNA. Each of the cell lines HeLa (HPV 18) and CaSki (HPV 16) displayed strong expression. Although these cell preparations were not identical to those of the patient samples, the results were comparable to those in the cases of squamous carcinoma. No measurable staining of peripheral blood lymphocytes by cytokeratin was observed. Thus, as indicated below, these cells lines do in fact reflect many of natural physical traits of tumor cells in vivo and can be used for further similar studies.

The relationship of filaggrin expression to histologic type was found to be inversely related to the level of cellular differentiation. Samples of cervical tissues with normal histologic features demonstrated the highest level of filaggrin staining, followed by a marked decrease in the mean fluorescence of the cases of condyloma acuminatum. Examples of grade 1 cervical intraepithelial neoplasia cases had a mean fluorescence for filaggrin only slightly less than that for condyloma acuminatum, whereas samples of grades 2 and 3 cervical intraepithelial neoplasia showed a further decrease in filaggrin expression. Expression of filaggrin was very low but greater than background in the cases of squamous cell carcinoma and in the cervical carcinoma cell lines. Immunohistochemical staining of formalin-fixed tissue sections could qualitatively distinguish between normal and grades 1 and 2 cervical intraepithelial neoplasia lesions and between grade 3 cervical intraepithelial neoplasia and squamous cell carcinoma but could not quantitatively separate further between histologic groups (data not shown).

Expression of the proliferative cytokines epidermal growth factor and transferrin receptors and cytoplasmic IL-1. The expression of the proliferative markers epidermal growth factor receptor, transferrin factor receptor, and IL-1 and measured by flow cytometry is shown in Fig. 3. Transferrin receptor and cytoplasmic IL-1 had measurable fluorescence in all cases from all histologic groups, which increased only slightly in cases of squamous cell carcimona. The expression of transferrin receptor in cases of grade 3 cervical intraepithelial neoplasia and squamous cell carcinoma were at least twice as great as for the other histologic groups. IL-1 and transferrin receptor in Hela and CaSki cells were slightly less than those of the squamous cell carcinoma but were also greater than those of the low-grade and moderate-grade dysplasias.

The expression of epidermal growth factor receptor

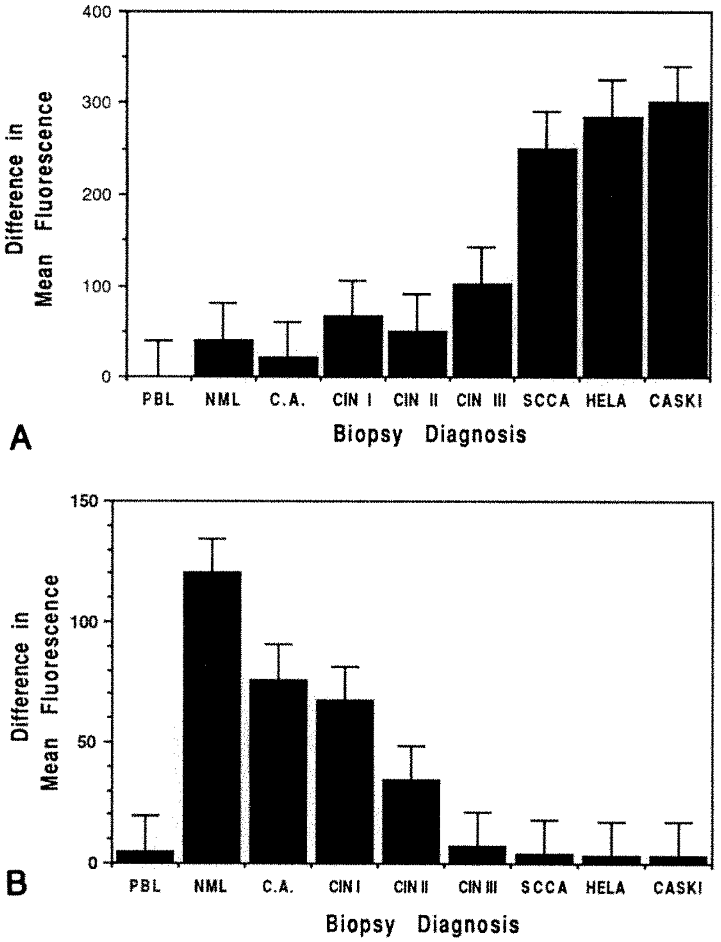

Fig. 2. Expression of structural cytoplasmic proteins cytokeratin (CAM 5.2) and filaggrin in exfoliated cervical tissue. Samples of cervical cells were stained with either antifilaggrin or anticytokeratin antibodies and analyzed by flow cytometry. Data presented are calculated from difference in mean fluorescence of sample from that of negative control: Sample − Control/Control. *Error bars* represent ± SEM. **A,** Cytokeratin expression. **B,** Filaggrin expression. *PBL,* peripheral blood lymphocyte; *NML,* normal; *CIN,* cervical intraepithelial neoplasia; *SCCA,* squamous cell carcinoma.

increased significantly in tissues showing higher grades of dysplasia and squamous cell carcinoma and in HPV-infected cell lines. The fluoresence for low-grade lesions (condyloma acuminatum and grade 1 cervical intraepithelial neoplasia) was twofold greater than that of normal samples, and the difference between these groups was not significant ($p > 0.1$). In the grade 3 cervical intraepithelial neoplasia and squamous cell carcinoma groups the relative expression levels of epidermal growth factor receptor were six to seven times those of normal samples ($p < 0.05$). These data demonstrate that the expression of epidermal growth factor receptor correlates with the severity of the histologic grade. Similarly, the expression of epidermal growth factor receptor in Hela and CaSki cells was comparable to that of the samples of squamous cell carcinoma.

In observations that were similar to those with cytokeratin and filaggrin, immunohistochemistry for epidermal growth factor receptor could only qualitatively distinguish low-grade from high-grade neoplasias; this is shown in Fig. 4, *A* and *B*. Immunohistochemistry was generally found not to be sensitive enough to show the differential staining intensity that was observed with flow cytometric analysis; these results are similar to those for the markers cytokeratin and filaggrin. Instead, tissue sections stained for epidermal growth factor receptor had no identifiable staining for either the normal or the condyloma acuminatum histologic group. An example of a grade 1 cervical intraepithelial neoplasia lesion is shown in Fig. 4, *A*, which demonstrates membranous localization of epidermal growth factor receptor in the proliferting basal and parabasal cells. Fig. 4, *B*, by contrast, reveals intense membranous outlining by the epidermal growth factor receptor protein, which was present in cells throughout the full thickness of the epithelium in grade 3 cervical intra-

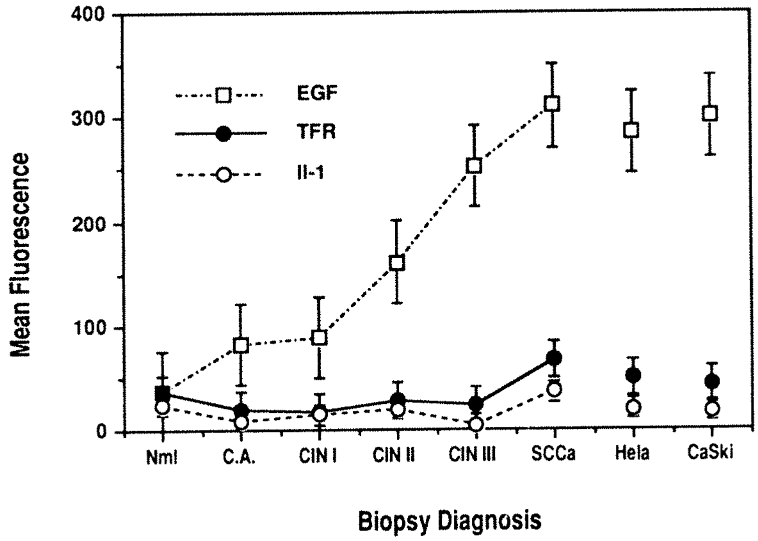

Fig. 3. Expression of cellular markers of proliferative epidermal growth factor receptor, transferrin receptor, and cytoplasmic IL-1. Shown on left are results from normal and neoplastic cervical cell samples *(points connected by lines)* and on right, from two cervical carcinoma–derived cell lines containing HPV DNA. Samples of cervical cells were stained with anti–epidermal growth factor receptor, anti–transferrin receptor, and anti–IL-1 and analyzed by flow cytometry. Data presented are calculated from difference in mean fluorescence of sample from that of negative control: (Sample − Control/Control). *Error bar* represents ±SEM. *Nml*, Normal; *C.A.*, condyloma acuminatum; *CIN*, cervical intraepithelial neoplasia; *SCCA*, squamous cell carcinoma; *EGF*, epidermal growth factor; *TFR*, transferrin factor receptors.

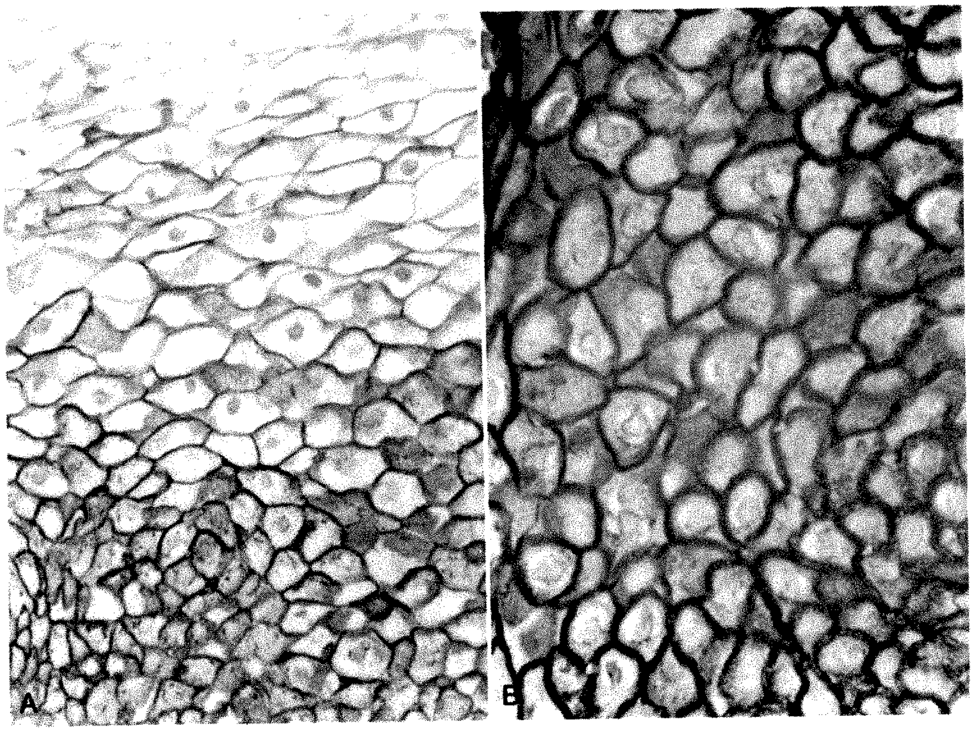

Fig. 4. Immunohistopathologic results of cervical biopsy tissue sections. **A,** Immunohistochemical staining with anti–epidermal growth factor receptor of grade 1 cervical intraepithelial neoplasia lesion showing outlining of membranous epidermal growth factor receptors in basal and focally in parabasal cell layers. (Original magnification ×325.) **B,** Anti–epidermal growth factor receptor staining of grade 3 cervical intraepithelial neoplasia lesion demonstrating intense membranous and focally granular cytoplasmic staining of full thickness of epithelium. (Original magnification ×400.)

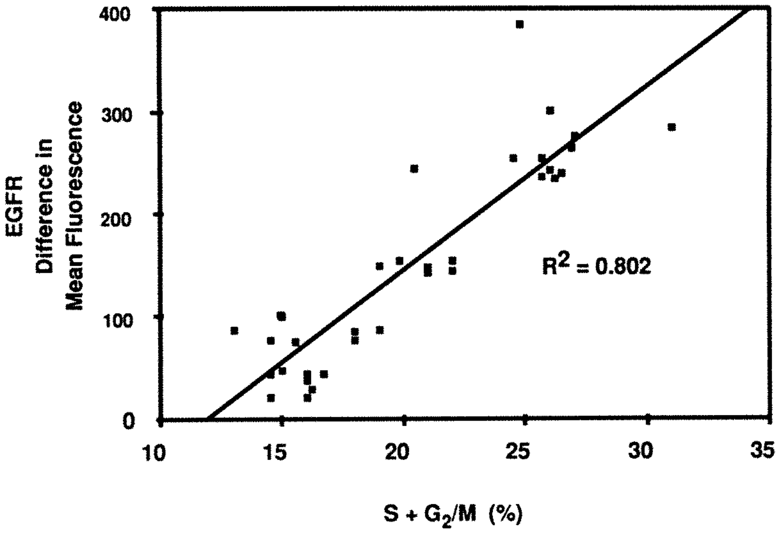

Fig. 5. Correlation of epidermal growth factor receptor expression and proliferative index by linear regression analysis. Mean fluorescence of epidermal growth factor receptor staining by flow cytometry was correlated with respective proliferative index of each sample and analyzed by simple linear regression. Analysis reveals linearity of data with high degree of correlation ($r = 0.802$). *EGFR*, Epidermal growth factor receptor.

epithelial neoplasia. Thus, although distinct differences in the intensity of staining for the epidermal growth factor receptor for varying histologic grades are possible, immunohistochemistry was relatively insensitive to the lower levels of expression of these markers that could be detected and quantified by flow cytometry.

Because of the wide range of fluorescence for the epidermal growth factor receptor in low-grade and high-grade neoplasias, it might be postulated that it was present at higher levels in dividing versus quiescent cells. Flow cytometric analysis of forward and side scatter parameters, which are measures of cellular size and internal complexity, demonstrated a uniform pattern for entire populations of cells. As seen in Table II, the proportion of cells in the proliferative phases of the cell cycle for squamous cell carcinoma is 1.6 times that of normal cells, while the expresison of epidermal growth factor receptor is increased sevenfold. Although no attempt was made to simultaneously analyze samples for epidermal growth factor receptor expression and proliferative index, a regression analysis of these two parameters was performed on data from the individual samples; this is illustrated in Fig. 5. The correlation of epidermal growth factor receptor and the proportion of S + G_2/M phase cells was found to be linear with a high level of significance ($r = 0.802$). Thus the compilation of these data suggests that epidermal growth factor receptor is correlated with both papillomavirus infection and severity of histologic grade and that biologically this marker is related to a increased proliferative index.

Comment

Autocrine and paracrine stimulation of cell surface receptors by growth factors is one mechanism by which epithelial cells are maintained in a state of cell division. Epidermal growth factor and transferrin factor are two cytokines important to the proliferation of normal keratinocytes and ectocervical cells, whereby the expression of the cell surface receptors for these factors is correlated with the level of cellular proliferation.[13] Similarly, cytoplasmic vesicles containing IL-1 are present in high levels in rapidly dividing epidermal tissue in certain disease states, and IL-1 by itself can stimulate cellular division in an autocrine manner.[22] To study the role of these selected markers of proliferation, we have used flow cytometric measurement of these factors on samples of exfoliated cervical cells from a cohort of patients with normal, dysplastic, and malignant cervical lesions, as well as continuous cell lines containing HPV DNA. Flow cytometric analysis offers a greater degree of sensitivity and a quantitative measure for these membrane and cytoplasmic proteins not available with conventional histochemical methods. In combinaton with DNA hybridization and DNA cell-cycle analysis, we have been able to uniquely examine several parameters of cellular growth and differentiation in a series of normal and HPV-associated cervical lesions.

Flow cytometry is a highly sensitive technique for the simultaneous analysis of a population of cells for membrane and cytoplasmic proteins, as well as for the analysis of the cell cycle. Cytoplasmic proteins such as filaggrin and cytokeratin are markers of cellular differentiation and have been shown to be predictive of the neoplastic conversion of cervical epithelium.[1] In this study low-molecular-weight cytokeratin was strongly expressed in a series of samples of cervical cells showing high histologic grade and was correlated with the HPV DNA of types 16, 18, and 31, whereas filaggrin was detected in normal cervices or low-grade cervical lesions. The evaluation of the full spectrum of expression of the cytokeratins and other related intermediate filaments in cervical tissues has been reported, and these studies concur with our own that alteration of the cytoskeletal filaments is a component of the neoplastic process.

The proliferative activity of a population of cells is related to the level of the expression of cytokines or their receptors and may also be one of the mechanisms by which papillomavirus gene products modify cellular processes leading to neoplastic transformation. Transferrin factor receptor is a ubiquitous marker of cell proliferation and one of the earliest signals in subsequent events leading to cell mitosis.[23] The expression of transferrin factor receptor was increased slightly in samples from high-grade dysplasias infected with papillomaviruses. Similarly, the expression of IL-1, which stimulates epidermal cell growth in an autocrine manner in certain disease states,[22] increased slightly over the spectrum of normal and HPV-infected cervical tissues.

Epidermal growth factor receptor was differentially expressed in cervical tissue, increasing with high histologic grade, and associated with a higher proliferative index. Increased expression of epidermal growth factor receptor expression on the cell surface is known to occur in several epithelial neoplasms.[24] A truncated form of the epidermal growth factor receptor has been described and shown to be expressed at high levels in cell lines derived from a squamous cell carcinoma of the vulva and in certain breast and kidney tumors.[12] This form of the epidermal growth factor receptor is neither transcribed to a greater amount nor more resistant to degradation but rather has been shown to be defective in its ability to be internalized and recycled to the cell surface after the binding of epidermal growth factor. A relationship between epidermal growth factor receptor expression and HPV infection has been reported in a select group of mucosal and cutaneous lesions.[13] Our data suggest that by using flow cytometry we can increase the sensitivity of the measurement of the epidermal growth factor receptor and to a lesser degree transferrin factor receptor and IL-1, we have found its measurement to vary significantly over the complete spectrum of HPV-associated lesions of cervical epithelium, including squamous cell carcinoma. Recently, it has been demonstrated that the E5 open reading frame of bovine papillomavirus type 1, which encodes a small hydrophobic protein with potent transforming activity in cultured rat fibroblasts, interacts with the epidermal growth factor receptor and other growth factor receptors in some way that leads to the constitutive phosphorylation of receptor proteins and inhibits its normal down regulation.[25] The observation that epidermal growth factor receptors in human cervical samples are similary expressed to higher levels in premalignant and malignant cells demonstrates that a similar process is at play in naturally arising HPV-associated lesions.

Hemostatic wrapping of ruptured liver in two postpartum patients

Andrew B. Rittenberry, Jr., MD,[a] Colman L. Arnold, MD,[a] and M. Mark Taslimi, MD[b]
Chattanooga, Tennessee

A variety of surgical techniques with variable success rates have been reported in the management of the spontaneously ruptured liver in pregnancy. We managed two cases of postpartum ruptured liver by wrapping the liver in hemostatic material. Hemostatic encapsulation effectively controlled massive bleeding of ruptured livers in two postpartum patients. (Am J Obstet Gynecol 1991;165:705-7.)

Key words: Ruptured liver, preeclampsia, hemostatic wrapping

Spontaneous rupture of the liver occurs estimately in 0.4 per 100,000 pregnancies and is associated with high maternal and fetal mortality and morbidity.[1, 2] In recent years prompt diagnosis and surgical intervention and intensive supportive measures have improved the survival rate of pregnant patients with ruptured livers. In a review by Smith et al.,[2] a variety of surgical techniques for management of spontaneously ruptured liver in pregnancy were reported. In two consecutive patients 6 years apart, with spontaneously ruptured livers in the postpartum period, we used similar hemostatic wrapping techniques to control massive bleedings. We searched the English-language literature of the past 25 years through MEDLINE Computer program with the use of a variety of relevant key words and did not find any reports on hemostatic wrapping of ruptured liver during pregnancy or the postpartum period.

Case reports

Case 1. A 24-year-old primigravid woman was first seen at term gestation with signs and symptoms of severe preeclampsia including nausea, vomiting, and right upper-quadrant pain. Pregnancy was terminated with an uneventful cesarean section. Hypovolemic shock developed 30 minutes after the operation. At laparotomy 2500 ml of fresh blood and blood clots were found in the abdomen. A 6 cm hemorrhaging laceration along the inferior anterior aspect of the right lobe and two subcapsular hematomas of the right and the

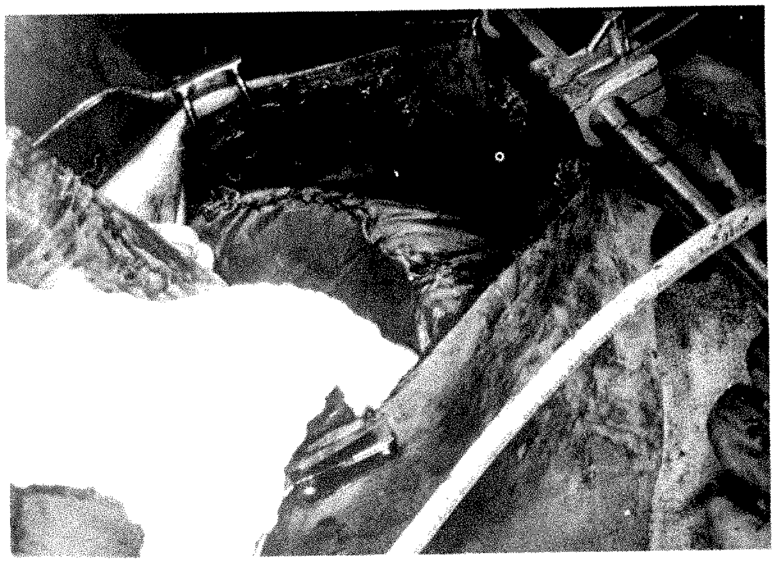

Fig. 1. The ruptured liver was released from its ligamentous attachments and encapsulated in a sheet of Vicryl suture mesh.

left lobes were initially treated with conventional surgical techniques including Pringle's maneuver, suturing and packing of the bleeding points, and later in a second laparotomy by right hepatic artery ligation. However, bleeding from the liver resumed, and after arteriography the patient was returned to the operating room. A latticework or net was fashioned from 5 mm Mersilene strip ligatures. Both hepatic lobes were completely mobilized from their diaphragmatic and peritoneal attachments and the net was snugly fitted and tied around the liver, which had been covered by strips of Surgicel gauze. Another laparotomy was done 24 hours later to control subsequent bleeding from the right adrenal gland; the liver was no longer bleeding. The postoperative course was complicated by disseminated coagulopathy, respiratory distress syndrome, prolonged hospitalization, and hepatitis B. Overall, the patient received 120 units of whole blood and blood products. At the time of a cholecystectomy 2 years later, the gross liver structure appeared to be normal. The Mersilene strip ligature net was intact with few adhesions.

Case 2. A 34-year-old, gravida 4, para 4 woman had spontaneous rupture of the liver 24 hours after delivery of an apparently uncomplicated term pregnancy. Laparotomy revealed a large amount of fresh blood and blood clots in the abdomen. The liver was grossly edematous and had hematomas and hemorrhaging tears on the anterior aspects of the right and left lobes. The liver was mobilized from its ligamentous attachments. The left lobe was wrapped snugly in a large sheet of Vicryl suture mesh. A larger sheet was fashioned by sewing two pieces of Vicryl suture mesh together, which was then wrapped around the right lobe. The sheets were sewn to each other and around the entire liver, leaving outlets for hepatic veins and porta hepatis (Fig. 1). The gall bladder was removed for ease of operation. The postoperative course was complicated by bilateral pleural effusion, transient paralytic ileus, and readmission for right pleural effusion. Two weeks after the operation, a computerized tomography scan showed a stable hematoma surrounding the anterior aspects of both lobes of the liver.

Comment

Disastrous outcome of the untreated spontaneous rupture of the liver in pregnancy has prompted introduction of a variety of classic and novel surgical management techniques.[2] Encapsulation of trauma-related, ruptured solid organs has been previously reported in surgical annals. However, we have not found any reports in English-language literature of the past 25 years on hemostatic wrapping of a ruptured liver during pregnancy or the postpartum period. We used hemostatic encapsulation of the ruptured liver in two postpartum patients, and found the technique to be a relatively easy and very effective operative method. The first patient had preeclampsia and disseminated coagulopathy, and did not respond to a variety of conventional surgical techniques. Hemostatic wrapping successfully stopped the bleeding from multiple hematoma and rupture sites of both hepatic lobes. With experience gained from the first case, the second patient with ruptured liver was expediently managed by hemostatic wrapping of the ruptured liver in sheets of absorbable Vicryl suture mesh. Elective cholecystectomy added to the ease of the operation. We believe that hemostatic wrapping can effectively control the bleeding from a spontaneously ruptured liver in postpartum patients, and may be considered as the first line of surgical management in such patients. Further experience is needed to clarify the usefulness of the method.

Relationship between fetal biophysical activities and umbilical cord blood gas values

Anthony M. Vintzileos, MD, Alfred D. Fleming, MD, William E. Scorza, MD, Edward J. Wolf, MD, James Balducci, MD, Winston A. Campbell, MD, and John F. Rodis, MD

Farmington, Connecticut

In a prospective study of 62 patients undergoing cesarean section before the onset of labor a fetal biophysical profile assessment was performed within 3 hours before the cesarean section. The presence or absence of the individual fetal biophysical activities (fetal heart rate reactivity, fetal breathing movements, fetal body movements, and fetal tone) were correlated with umbilical cord blood gas and acid-base measurements (artery and vein). Fetuses with nonreactive nonstress test results or the absence of breathing had significantly lower cord artery pH, Po_2 bicarbonate, and base excess measurements but not a significantly different Pco_2 level as compared with fetuses that had these activities present. Fetuses with the absence of movements or tone had lower pH, Po_2 bicarbonate, and base excess levels and higher Pco_2 levels as compared with fetuses with the presence of movements or tone, respectively. These blood gas and acid-base differences were observed in both umbilical cord artery and vein. Subsequent analysis of the blood gas and acid-base measurements of the fetuses with compromised biophysical activities revealed that there are different levels of acidemia, hypoxemia, and hypercapnia at which the individual biophysical activities are compromised. These data suggest that the first manifestations of fetal hypoxemia and acidemia are nonreactive nonstress test results and loss of fetal breathing; in advanced acidemia, hypoxemia, and hypercapnia fetal movements and fetal tone are compromised. (AM J OBSTET GYNECOL 1991;165:707-13.)

Key words: Fetal biophysical activities, cord blood gas values

Previous studies from our institution have suggested that there is a significant relationship between fetal biophysical assessment and fetal acidemia as determined by umbilical cord pH value at the time of testing.[1] These studies, which used only cord blood pH measurements, also suggested that the first manifestations of fetal acidemia are nonreactive nonstress test (NST) results and loss of fetal breathing, whereas in advanced acidemia fetal movements and fetal tone are compromised. However, the relationships between fetal biophysical assessment and the remaining blood gas and acid-base measurements, including Po_2, Pco_2, bicarbonate, and base excess, have not been investigated in the human fetus.

This prospective study was therefore undertaken with the following objectives: (1) to investigate the relationship between the presence or absence of the in-

dividual fetal biophysical activites and umbilical cord blood gas measurements (pH, Po_2, Pco_2, bicarbonate, and base excess) in both artery and vein, and (2) to determine the different levels of pH, Po_2, Pco_2, bicarbonate, and base excess at which the individual biophysical activities become compromised.

Material and methods

This prospective study included 62 consecutive patients with singleton pregnancies, gestational ages between 25 and 37 weeks, and delivery by cesarean section before the onset of labor. Infants with congenital anomalies were excluded. In all cases fetal biophysical profile assessment and umbilical artery velocimetry were performed within 3 hours before the cesarean section. The relationship between fetal biophysical assessment, umbilical artery velocimetry, and fetal acidemia in this group of patients was investigated and is reported separately.[2] The primary indications for delivery were severe pregnancy-induced hypertension (34 patients, 55%), severe pregnancy-induced hypertension associated with intrauterine growth retardation (14 patients, 22%), severe intrauterine growth retardation (8 patients, 13%), and placenta previa (6 patients, 10%). All patients had intact membranes and all received epidural analgesia. All cesarean sections were performed with the patient in the left lateral position. Epidural analgesia was achieved with 0.5% bupivacaine hydrochloride after infusion of 1000 ml lactated Ringer's injection solution. Nasal oxygen was administered 3 L/min from the time satisfactory blockade was achieved until delivery of the infant. None of the patients was hypotensive.

The fetal biophysical assessment was performed according to a previously described method with a maximum period of observation of 30 minutes.[3] For the purpose of this study, a nonreactive NST result was defined as one or fewer fetal heart rate (FHR) accelerations (15 beats/min for 15 seconds) in ≥ 40-minute period. Absence of fetal breathing was defined as the absence of at least one epsiode of fetal breathing lasting 30 seconds within 30 minutes. Absence of fetal

FT, Fetal tone. Measurements are expressed as mean ± SD.

body movements was defined as the presence of two or fewer fetal body movements within 30 minutes. Absence of fetal tone was defined as fetal extremities in extension without return to flexion after fetal body movements.

Immediately after delivery, a segment of the umbilical cord was doubly clamped and blood was collected separately from the artery and vein into plastic heparinized syringes. It was then transported on ice for acid-base analysis, which was done by means of an automatic pH and blood gas analyzer (model 178, Corning Medical, Boston). All pH measurements were performed within 5 minutes after the blood collection and all patients had samples drawn from both artery and vein. The pH, Po_2, and Pco_2 were directly measured whereas the bicarbonate and base excess levels were calculated. The comparison of blood gas values between fetuses with and without the presence of biophysical activites was performed with the Student *t* test. A one-tail *t* test was used to check for existing differences of the various blood gas levels at which the biophysical activities are compromised. A *p* value < 0.05 was considered statistically significant.

Results

The mean (±SD) gestational age was 31.9 (±3.1) weeks. On the basis of fetal biophsyical assessment before the cesarean section, 30 fetuses had nonreactive NST results, 24 had absence of breathing, nine had absence of body movements, and five had absence of tone. Tables I to IV compare the blood gas and acid-base measurements between fetuses with and without the presence of biophysical activities. As shown in Table I, fetuses with nonreactive NST results had significantly lower pH, Po_2, bicarbonate, and base excess levels as compared with fetuses with reactive NST results. There was no difference in the Pco_2 level between these two groups of fetuses. The same relationships were noted in both cord artery and vein measurements. As shown in Table II, fetuses with the absence of breathing also had lower levels of cord artery pH, Po_2, bicarbonate, and base excess but not significantly different Pco_2 levels as compared with fetuses with breathing present. Tables V and VI show the blood gas values of both the artery and vein at which the biophysical activities become compromised.

Figs. 1 to 5 illustrate the comparison of the cord

artery blood gas and acid-base measurements associated with the absence of biophysical activities. Although no differences were found between nonreactive NST results and the absence of fetal breathing, significant differences were found between either nonreactive NST results or the absence of fetal breathing versus the absence of fetal body movement or tone, as well as between absent fetal movement versus absent tone. The absence of fetal movements or tone was associated with lower pH, P_{O_2}, bicarbonate, and base excess levels and higher P_{CO_2} levels as compared with the absence of breathing or nonreactive NST results. Similar relationships were noted in both artery and vein measurements.

Comment

The purpose of antepartum fetal biophysical assessment is to avoid fetal death in utero and perhaps some hypoxic complications of the neonate related to intrauterine asphyxia. Because fetal asphyxia is the common end pathway to fetal death in many high-risk pregnancies, it is reasonable to investigate the ability of the individual biophysical components to detect the different degrees of fetal hypoxemia, hypercapnia, and acidemia. Although the relationship between fetal acidemia, as determined by cord blood pH measurements, and fetal biophysical assessment has been previously reported by our group,[1] we are not aware of data regarding the different levels of fetal hypoxemia or hypercapnia at which the biophysical activities become compromised. The purpose of this investigation was to investigate the relationship of the individual biophysical components and fetal hypoxemia, hypercapnia, and acidemia as determined by umbilical cord blood gas and acid-base measurements. In our previous study[1] we examined only the relationship between biophysical assessment and cord blood pH value. With this study we extend our observations to the relationship between the individual biophysical components and the remaining blood gas values (P_{O_2}, P_{CO_2}, bicarbonate, and base excess). This study design was such that all patients re-

ceived the same technique to induce anesthesia (epidural) so that comparisons of the blood gas values between the different groups were possible and appropriate.

These data suggest that the acute markers of the fetal conditions (FHR reactivity, fetal breathing movements, fetal body movements, and fetal tone) are strongly correlated with fetal acid-base status at the time of testing including not only pH but also most of the other acid-base parameters. The presence of FHR reactivity (reactive NST results) and the presence of fetal breathing were always associated with cord blood pH values greater than 7.20. As shown in Tables I to IV, the presence or absence of the acute markers of fetal condition is related to fetal acid-base status at the time of testing. The absence of FHR reactivity (nonreactive NST results) and the absence of fetal breathing were associated with lower levels of pH, Po_2, bicarbonate, and base excess as compared with the presence of these activities. However, we found no significant differences in the Pco_2 levels between reactive and nonreactive NST results or between presence or absence of fetal breathing. Absence of fetal body movements or tone was associated with significantly lower pH, Po_2, bicarbonate, and base excess levels and higher P_{CO_2} levels as compared with the presence of these activities. These observations, in combination with the much lower pH and P_{O_2} levels that were observed in fetuses with the absence of movements and tone, would strongly suggest that hypercapnia is a relatively late event in the development of antepartum intrauterine asphyxia. These data suggest that the first clinical manifestations of fetal hypoxemia and acidemia are nonreactive NST results and loss of fetal breathing. In advanced acidemia, hypoxemia, and hypercapnia, fetal body movements and fetal tone are compromised.

Our previous study[1] has provided information regarding the pH level below which the fetal central nervous system centers malfunction. Our previous data have suggested that the FHR reactivity and fetal breathing centers cease when the pH is lower than 7.20; the centers controlling body movement and tone begin to malfunction at pH values of 7.10 to 7.20 and are completely abolished at a pH level lower than 7.10. This study extends our observations and establishes the levels of all other remaining acid-base parameters including pH, P_{O_2}, P_{CO_2}, and base excess, at which the biophysical activities become compromised (Tables V and VI). Our present observations support the concept of different levels of sensitivity not only to acidemia but also to hypoxemia and hypercapnia. The concept of nonreactive NST results and the absence of fetal breathing being one of the first manifestations of fetal hypoxemia and acidemia, whereas the absence of fetal body movements and tone indicate the presence of advanced acidemia, hypoxemia, and hypercapnia is very important for correct interpretation and application of the information obtained from fetal biophysical monitoring.

Amniotic fluid volume, unlike the fetal biophysical activities, is not influenced acutely by alterations in fetal acid-base status and represents a chronic marker of the fetal condition. We still include amniotic fluid assessment in the fetal biophysical profile because of the high correlation between decreased amniotic fluid volume and increased incidence of abnormal pregnancy outcome.[3, 4]

These data suggest that sequential assessment of the individual biophysical components makes sense as we have proposed in the past.[5] The different sensitivity levels of the individual biophysical activities apply not only to different degrees of acidemia but also to different degrees of hypoxemia and hypercapnia. In the presence of reactive NST results or fetal breathing, there is nothing to be gained by also assessing body movements and tone. On the other hand, in the absence of FHR reactivity and breathing it is important to assess the presence of body movements and tone because if these activities are also absent then one should suspect advanced acidemia, hypoxemia, and hypercapnia. The understanding of the physiology and pathophysiology of the fetal biophysical activities is essential for estimating the degree of fetal compromise and a prerequisite for the appropriate clinical applicaton of fetal biophysical assessment.

Twelve fetuses were evaluated with a combination of ultrasonography, amniocentesis, and blood sampling for possible cytomegalovirus infection. In seven the mother had a documented primary cytomegalovirus infection. All seven women had normal ultrasonographic findings and one fetus was found to be infected. In the other five cases fetal cytomegalovirus infection was diagnosed in association with abnormal ultrasonographic findings. There was no history of maternal infection in the latter group. All positive and negative diagnoses were confirmed and none of the six infected fetuses survived. In this series, the most reliable parameters of infection were the isolation of the virus from amniotic fluid and elevations of total immunoglobulin M and γ-glutamyl transpeptidase in fetal blood. In the majority of infected fetuses cytomegalovirus-specific immunoglobulin M was not detected in blood. Prenatal diagnosis of fetal cytomegalovirus infection is possible with a combination of amniocentesis and fetal blood sampling. (AM J OBSTET GYNECOL 1991;165:714-8.)

Key words: Cytomegalovirus, prenatal diagnosis, fetus

Cytomegalovirus is the most common cause of intrauterine infection, affecting an estimated 1% of all live births in the United States.[1] Fetal infection may follow either primary or reactivated maternal infection, although symptomatic congenital disease is more likely to occur in association with primary maternal infection.[2] A total of 30% to 40% of pregnant women with primary cytomegalovirus infection transmit the virus to their fetuses.[3] Although only 10% of those infected are symptomatic at birth, 20% to 30% die and late complications almost invariably develop among the survivors. In addition, long-term neurologic sequelae develop later in childhood in 5% to 15% of congenitally infected infants without symptoms.[4]

The natural history of intrauterine cytomegalovirus infection is not well understood, but it is clear that some fetuses are irreversibly damaged by the virus before delivery. Those infants would not derive much benefit from postnatal therapy, but if infected fetuses could be detected before this irreversible stage has been reached, treatment in utero might have a significant effect on the course of the disease. The recent development of effective antiviral agents with in vitro and in vivo activity against human cytomegalovirus may make such therapy possible.[5] Daffos et al.[6] have shown that in utero treatment of fetuses infected with toxoplasmosis significantly improves the outcome in those cases. However, before consideration can be given to treatment of cytomegalovirus in utero, it is necessary to be able to accurately diagnose fetal infection with this organism. In addition to traditional fibroblast cultures, new methods including the use of monoclonal antibodies, deoxyribonucleic acid (DNA)–ribonucleic acid (RNA) hybridization and DNA amplification by the polymerase chain reaction have been applied to the rapid diagnosis of cytomegalovirus infection. The sensitivity and specificity of these methods in the detection of fetal infection remains to be determined. This article describes our experience with the prenatal diagnosis of cytomegalovirus infection in 12 fetuses with either exposure to documented primary maternal infection during pregnancy or abnormal ultrasonographic results suggestive of fetal cytomegalovirus infection.

Material and methods

Patients at risk of fetal cytomegalovirus infection were evaluated at the Mount Sinai Medical Center or the Institut de Puericulture de Paris between 1982 and 1989. Seven women were seen because of documented primary maternal cytomegalovirus infection, and five additional patients were investigated because of abnormal ultrasonographic findings suggestive of fetal infection. All patients underwent detailed ultrasonographic examinations and 11 of the 12 also had percutaneous fetal blood sampling and simultaneous amniocentesis. Amniotic fluid was cultured for cytomegalovirus. Complete blood cell count, γ-glutamyl

transpeptidase (GGTP), total immunoglobulin M (IgM), cytomegalovirus-specific IgM, and cytomegalovirus cultures were performed on the fetal blood samples. In addition, polymerase chain reaction with cytomegalovirus-specific oligonucleotides was performed on two amniotic fluid and fetal blood samples obtained at the Mount Sinai Medical Center.

All cytomegalovirus cultures, specific IgM assays, and polymerase chain reaction studies of those fetuses evaluated at the Mount Sinai Medical Center were performed in the laboratory of one of the authors (D.E.) at Memorial Sloan-Kettering Cancer Center. Cytomegalovirus-specific IgM was determined by enzyme-linked immunosorbent assay (ELISA). Cytomegalovirus isolation was performed in fibroblast culture by indirect immunofluorescence staining with cytomegalovirus-specific monoclonal antibodies. Results were generally available within 48 hours after innoculation. The polymerase chain reaction studies on amniotic fluid and fetal blood were performed by previously described techniques.[7] We used oligonucleotide primers flanking a 421 base pair sequence of the cytomegalovirus immediate-early gene and an oligonucleotide probe to an internal sequence of the amplified sequence. Positive and negative controls were analyzed simultaneously with each study sample. Specific details regarding the polymerase chain reaction primers and probe and the cytomegalovirus-specific monoclonal antibodies will be furnished on request.

At the Institute of Puericulture de Paris, cytomegalovirus-specific IgM studies were also performed by ELISA. Cytomegalovirus cultures were done by fibroblast innoculation without immunofluorescence, and results were available within 3 to 4 days after innoculation.

Complete blood counts were done by standard automatized techniques, and all abnormal platelet counts were confirmed manually. Total IgM and GGTP were assayed by standard techniques at both centers. Hematocrit values, platelet counts, and total IgM values were compared with normal fetal values for the corresponding gestational age.[8] GGTP levels do not change with gestational age, and the values in this series were compared with known fetal norms (24.4 ± 9.6 UI/L).[9]

Fetal blood sampling was done percutaneously under ultrasonic guidance, and amniotic fluid was obtained immediately after the blood had been aspirated. The fetal origin and purity of the blood was confirmed in all cases by red blood cell size analysis.

Results

Primary infections. Seven pregnancies were studied because of documented primary infections in the mothers (Table I, patients 1 to 7). All these women had clinical manifestations of cytomegalovirus infection, and cytomegalovirus-specific IgM present in their serum. The infections all occurred during the first half of pregnancy (range, 11 to 18 weeks), and the patients were referred for fetal assessment between 21 and 32 weeks' gestation. One of these fetuses was found to be infected with cytomegalovirus. This case (Table I, No. 1) has been previously reported.[10] Briefly, the mother had fever, neurologic symptoms, and liver dysfunction at 11 weeks' gestation and she was shown to have cytomegalovirus-specific IgM. At 21 weeks' gestation ultrasonographic examination revealed an appropriately grown fetus and no structural abnormalities or evidence of hydrops. Fetal blood studies revealed a normal hematocrit value and platelet count, and cytomegalovirus-specific IgM was absent. The GGTP value was elevated, however, and cultures of the amniotic fluid and fetal blood were positive for cytomegalovirus. This pregnancy was terminated. Autopsy revealed a grossly normal fetus with histologic evidence of nonspecific acute infection (white cell infiltrates in the lung and liver). There were rare inclusion cells suggestive of cytomegalic inclusion disease. Immunofluorescence tissue studies were positive for cytomegalovirus in the fetal kidney, lung, adrenal, and placenta.

The six remaining fetuses of mothers with documented infection were sampled between 24 and 32 weeks' gestation. All were structurally normal on ultrasonographic examination. The fetal hematocrit, platelet count and total IgM levels were normal. Specific cytomegalovirus IgM and viral cultures of amniotic fluid and fetal blood were negative in all cases. These fetuses were delivered at term, and all except one were appropriately grown. None had manifestations of cytomegalovirus infection. Specific IgM and viral cultures were negative in all neonates.

Abnormal ultrasonographic findings. Five additional fetuses were studied because of abnormal ultrasonographic findings and all were infected. None of these five fetuses survived; three pregnancies were terminated and the two live-born infants died within a few days (Table I, patients 8 to 12). Patient No. 9 did not undergo amniocentesis or fetal blood sampling. In this instance the pregnancy was terminated because of the ultrasonographic findings and the diagnosis was made retrospectively by culturing tissues from the abortus. In all five cases cytomegalovirus infection was confirmed by isolation of the virus from fetal tissues after termination of pregnancy or in the urine of live-born infants during the first week after birth. All the mothers were cytomegalovirus IgG seropositive but none had cytomegalovirus-specific IgM. Therefore it is likely that these cases were a result of recurrent infection, although a primary infection earlier during the pregnancy cannot be ruled out. One case was confirmed to

be a recurrence because at 10 weeks' gestation the mother was found to have cytomegalovirus-specific IgG and no IgM.

The ultrasonographic findings in this group were varied. The most common abnormalities were ventricular dilatation (three cases) and oligohydramnios (three cases). One fetus (patient No. 10) was thought to be growth retarded, and this was the only one with a birth weight below the 10th percentile. Not only were the ultrasonographic findings diverse among the patients, but in a given fetus they sometimes changed. For example, in the fetus of patient No. 8 moderate ascites at 22 weeks' gestation resolved almost completely within 1 week.

Comment

Approximately 10% of infants congenitally infected with cytomegalovirus are symptomatic at birth.[4] The most common findings are petechiae, hepatosplenomegaly, jaundice, microcephaly, small size for gestational age, inguinal hernias in males, and chorioretinitis. The mortality in this group may be as high as 30%, and 90% of the survivors have permanent disabilities such as mental retardation, neuromuscular disorders, and hearing loss. Permanent sequelae, which is usually hearing loss, develop in 5% to 15% of the infected infants without symptoms, but mental retardation and severe neuromuscular disorders may also occur.[4, 11]

Between 30% and 40% of infants exposed to primary maternal cytomegalovirus infection will be congenitally infected.[3] It is not known why most exposed fetuses do not acquire the infection. Gestational age at the time of maternal infection does not affect the transmission rate, although it does seem to influence the severity of the infection. In the report by Stagno et al.[3] of 37 infected infants, all those who were symptomatic at birth and those in whom clinically significant handicaps subsequently developed were born to women with primary infection before 27 weeks' gestation.

If 1% of all babies delivered in the United States are congenitally infected, and approximately 20% of these have permanent sequelae, it is obvious that cytomegalovirus is a significant public health problem. Surprisingly, there are only a few isolated reports regarding the prenatal diagnosis of this infection.[12] The most obvious explanation for this is that the great majority of primary cytomegalovirus infections are without

symptoms, and pregnant women are not routinely screened for cytomegalovirus antibodies. Another problem is that there is no intrauterine treatment for this disease at this time.

In this series we evaluated seven fetuses exposed to documented primary maternal infection and found only one (14%) to be infected in utero. All these fetuses, including the infected one, had normal ultrasonographic findings. By combining viral cultures of amniotic fluid and fetal blood with assessment of specific cytomegalovirus IgM, total IgM, platelet count, and GGTP in fetal blood we were able to make a correct diagnosis in each of these cases. All negative cases were confirmed after birth and cytomegalovirus was isolated from the infected fetus after termination of that pregnancy. It must be noted, however, that given the normal morphologic findings in the infected fetus it is impossible to predict what manifestations if any may have occurred after birth in that case.

Five infected fetuses were evaluated because of abnormal ultrasonographic findings. The most common finding in this group was cerebral ventricular dilatation and oligohydramnios. However, no single abnormality was consistently seen in all fetuses. Clearly, any fetus with ventricular dilatation, microcephaly, or cerebral calcifications should be suspected of being infected. Also, fetuses with any evidence of unexplained hydrops (ascites, pleural effusions, or skin edema) should be evaluated for cytomegalovirus infection. None of the fetuses with abnormal ultrasonographic findings and cytomegalovirus infection survived; three pregnancies were terminated and the two live-born infants died within a few days. All these fetuses were found to have severe manifestations of cytomegalovirus infection including three with central nervous system abnormalities. The other two had normal central nervous system findings but died of pulmonary hypoplasia and liver failure.

Five of the six infected fetuses underwent fetal blood sampling and amniocentesis. A positive viral culture of amniotic fluid and elevated total IgM and GGTP values in fetal blood were found in all five fetuses tested. Cytomegalovirus culture of fetal blood was positive in only one of five fetuses tested. Cytomegalovirus-specific IgM was present in fetal blood in only one of the five fetuses tested, compared with rates of 50% to 90% found in cord blood of infected neonates.[13, 14] The fetal immune system has been found to be capable of consistently responding to certain antigenic stimuli by 22 weeks' gestation.[15] However, production of specific IgM appears to be dependent on the organism involved. For example, it has been found that the vast majority of fetuses with congenital rubella infection produce specific IgM after 22 weeks,[15] whereas only 15% of fetuses infected with toxoplasma tested between 24 to 29 weeks produce specific IgM.[6] The low rate of positivity in our patients may be because two of the patients were sampled at 21 and 23 weeks' gestation, or it may be related to the IgM assays used. Ahlfors et al.[13] sent serum from culture proved cytomegalovirus-infected neonates to four different laboratories for analysis. The three that used an ELISA detected cytomegalovirus-specific IgM in 63% to 80% of the cases, whereas the one with a radioimmunoassay detected positivity in only 50% of cases. Other authors[14] have reported that the radioimmunoassay is 90% sensitive. It is clear from all studies that viral cultures remain the "gold standard." In this report only ELISAs were used, but they were performed in two different laboratories. Because the number of patients is small, the true sensitivity of specific IgM analysis cannot be determined from this series, but it is evident that this parameter alone cannot be used to exclude congenital cytomegalovirus infection.

In conclusion, the prenatal diagnosis of cytomegalovirus infection is possible by use of a combination of ultrasonography, amniocentesis, and fetal blood sampling. Although amniotic fluid culture for cytomegalovirus seems to be very sensitive, the number of cases in this series is not large enough to advocate use of amniocentesis as the only diagnostic approach. Furthermore, in a review Stagno et al.[16] mentioned that they were aware of three women with primary gestational cytomegalovirus infection in whom the virus was isolated from fetal or placental tissues but not from amniotic fluid. In our opinion, until more data become available, fetal blood should also be studied when evaluating a fetus for cytomegalovirus infection. Furthermore, it is possible that fetuses with hematologic evidence of systemic involvement, such as thrombocytopenia and liver damage, may have a worse prognosis than those infected without these findings. Once the diagnosis has been made, if the fetus has abnormal ultrasonographic findings this series suggests that the prognosis for intact survival appears to be very poor. However, if the ultrasonographic findings are normal the prognosis is far from clear. Until follow-up data of such cytomegalovirus-infected fetuses are available, we will have to rely on information obtained from neonates about the natural history of these infants.

Increased inducibility of inflammatory mediators from peripheral blood mononuclear cells of women with salpingitis

Steven S. Witkin, PhD, Miklos Toth, MD, Jan Jeremias, AB, and William J. Ledger, MD
New York, New York

To investigate whether immune system activation may contribute to the tissue damage observed in salpingitis, we isolated peripheral blood mononuclear cells and quantitated production of the monocyte activation products tumor necrosis factor-α, interleukin-1, and interleukin-6. Unstimulated cells from 7 of 20 women with salpingitis spontaneously released tumor necrosis factor at a concentration >2 SD above the mean value produced by cells from 29 healthy donors. Interferon gamma (200 U/ml) further induced production of tumor necrosis factor from mononuclear cells of 11 women with salpingitis. In contrast, production of tumor necrosis factor by each of 23 other patients who lacked laparoscopic or clinical evidence of salpingitis was similar to that of the controls. In a subset of women whose cells were tested for production of other monokines, three of nine women with salpingitis spontaneously released interleukin-1 but none of the others did so. Four of nine patients with salpingitis also produced interleukin-6, but none of the others did so. None of the monokines were detected in serum from any subject. The results suggest that monocytes from women with salpingitis are primed in vivo and produce inflammatory mediators under conditions where monocytes from other women are poorly responsive. This increased monokine inducibility may contribute to the tubal damage that is the hallmark of salpingitis. (AM J OBSTET GYNECOL 1991;165:719-23.)

Key words: Salpingitis, tumor necrosis factor, monocytes, interleukin-1, interleukin-6, *Chlamydia trachomatis*

Acute salpingitis is a major cause of occlusion of the fallopian tubes and the subsequent occurrence of infertility and ectopic pregnancy. The microorganisms responsible for this disease, primarily *Neisseria gonorrhoeae* and *Chlamydia trachomatis,* and possibly a variety of other aerobic and anaerobic bacteria, have been identified.[1,2] However, the mechanism of tubal damage, especially in nongonococcal pelvic inflammatory disease, remains unclear. In organ cultures *C. trachomatis* does not visibly damage the fallopian tubes.[3] However, extensive tubal damage often may be observed in vivo in chlamydial pelvic inflammatory disease.[4]

The immune response to infection might be responsible for the tubal damage in chlamydial pelvic inflammatory disease. A single inoculation of *C. trachomatis* into the fallopian tubes of monkeys induced a transient limited infection. Repetitive inoculations, however, resulted in permanent tubal damage.[5] A 57 kd chlamydial protein, which cross reacts with heat shock proteins present in other bacterial species, has been shown to induce a potent delayed hypersensitivity response in animals previously exposed to *Chlamydia* sp.[6] Antibodies to this protein were detected in women with tubal infertility[2] and correlated with the occurrence of ectopic pregnancy in women with pelvic inflammatory disease.[7] Interferon gamma, a potent activator of cell-mediated immunity, also has been identified in the circulation of women with pelvic inflammatory disease.[8]

Products of activated monocytes and tissue macrophages, including tumor necrosis factor, interleukin-1, and interleukin-6, are potent mediators of inflammation and fibrosis.[9] Tumor necrosis factor and interleukin-1 promote infiltration by granulocytes, monocytes, and neutrophils to inflammatory sites. Interleukin-1 induces fibroblast growth and the synthesis of prostaglandin E_2 and collagenase. Tumor necrosis factor stimulates the production of toxic oxygen radicals, augments phagocytosis, interferes with epithelial cell growth, and induces interleukin-6 synthesis. Interleukin-6 induces acute phase protein synthesis and differentiation of monocytes and T and B lymphocytes.

Circulating unactivated (resting) monocytes from healthy individuals release little or no tumor necrosis factor, interleukin-1, or interleukin-6. However, if the monocytes are first exposed to interferon gamma, a product of activated T lymphocytes, or to microorganisms, they undergo a maturational change and become primed to produce monokines on subsequent exposure to low concentrations of lipopolysaccharide or bacteria that do not normally evoke a response in resting monocytes.[10]

We now report that peripheral blood mononuclear

Afer 20 hours, culture supernatants were collected and assayed for tumor necrosis factor. *Broken horizontal line,* Value 2 SDs above mean for healthy controls.

cells from women with salpingitis produce tumor necrosis factor-α, interleukin-1, and interleukin-6 under conditions where cells from women without salpingitis remain normally unresponsive. The results suggest that monocytes from patients with salpingitis may be primed in vivo to readily produce inflammatory mediators that may contribute to subsequent fallopian tube damage.

Material and methods

Subjects. The study population consisted of 20 patients with a current diagnosis of salpingitis and 23 other patients diagnosed with other gynecologic problems, including pelvic pain ($n = 4$), recurrent miscarriage ($n = 4$), unexplained infertility ($n = 4$), urinary tract infection ($n = 3$), recurrent vaginitis ($n = 2$), menorrhagia ($n = 2$), ovarian cyst ($n = 2$), and postpartum endometritis ($n = 2$). Controls were 29 reproductive-age women in apparently good health with no history of pelvic inflammatory disease or infection with *C. trachomatis* or *N. gonorrhoeae*. Salpingitis was diagnosed by laparoscopic surgery in 18 of the women who had visual evidence of tubal damage caused by an inflammatory process. Microbial cultures were not obtained during surgery. A differential diagnosis of salpingitis was made in two women who did not undergo laparoscopy, on the basis of the presence of adnexal tenderness, cervical motion tenderness, and identification of *C. trachomatis* in endocervical cultures. The four women with pelvic pain had no evidence of salpingitis during laparoscopy. The other patients did not undergo surgery.

Peripheral blood mononuclear cell incubation. Mononuclear cells were isolated from heparinized peripheral blood by Ficoll-Hypaque (Pharmacia, Piscataway, N.J.) gradient centrifugation and added to multiple wells of a microtiter plate (2×10^5 cells per well) containing 10% heat-inactivated autologous serum in RPMI 1640 medium with 25 mmol HEPES buffer, L-glutamine, penicillin (100 U/ml), streptomycin (100 pg/ml), and kanamycin (100 U/ml). Interferon gamma (Genzyme, Boston) was added to triplicate wells at a concentration of 200 units/ml. After incubation for 20

Peripheral blood mononuclear cells were incubated for 20 hours. Culture supernatants were collected and assayed for interleukin-1 or interleukin-6. *Underlined values* are >2 SDs above mean values for control group. *ND,* Not determined.

hours at 37° C in a 5% carbon dioxide incubator, culture supernatants were collected, particulate components were removed by microcentrifugation, and the supernatants were stored at $-70°$ C until used.

Monokine assays. Culture supernatants were assayed for tumor necrosis factor-α (Cistron, Pine Brook, N.J.), interleukin-1 (Cistron), and interleukin-6 (Genzyme) by enzyme-linked immunosorbent assays with commercially available kits. All samples were tested in triplicate and the mean value was determined. Replicates differed by <15%. Values were converted to picograms per milliliter by reference to a standard curve obtained by the simultaneous analysis of known concentrations of purified compounds in culture medium. The lower limit of sensitivity was 20 pg/ml for tumor necrosis factor and interleukin-1 and 0.2 ng/ml for interleukin-6.

Statistics. Differences in the numbers of women in each of the subject groups with elevated tumor necrosis factor production under the experimental conditions were evaluated by the χ^2 test, with the Yates correction factor.

Results

Spontaneous tumor necrosis factor production by peripheral blood mononuclear cells. The levels of tumor necrosis factor produced by unstimulated mononuclear cells from women with salpingitis, women with other disorders, and healthy controls are shown in Fig. 1. Only low levels of tumor necrosis factor were detected in the culture fluids of unstimulated cells from healthy women. A similar range of concentrations were detected in culture supernatants of mononuclear cells from women with disorders other than salpingitis. In marked contrast, mononuclear cells from seven of the 20 women with salpingitis spontaneously released tumor necrosis factor at levels >2 SDs above the control mean value. The difference in the number of women with elevated tumor necrosis factor production in the salpingitis and control groups was significant ($p < 0.01$).

Tumor necrosis factor production by peripheral blood mononuclear cells incubated with interferon gamma. In the presence of interferon gamma, mononuclear cells from only one of 23 patients with a diagnosis of a disorder other than salpingitis and one of 29 healthy controls produced tumor necrosis factor at a level >2 SDs above the control mean value. In marked contrast, interferon gamma–stimulated cells from 11 of 20 women with salpingitis produced tumor necrosis factor at elevated levels (Fig. 2). The number of women in the salpingitis group releasing elevated levels of tumor necrosis factor under these conditions was significantly greater than the number of women in the other groups ($p < 0.01$).

Interleukin-1 and interleukin-6 production by peripheral blood mononuclear cells from women with salpingitis. Mononuclear cells from nine patients diagnosed as having salpingitis, nine patients with other diseases, and 12 healthy controls also were tested for their ability to release two other monocyte products, interleukin-1 and interleukin-6. The upper limit of normal was designated as a value 2 SDs above the mean level of each monokine produced by peripheral blood mononuclear cells from the healthy controls; the number of patients whose unstimulated cells produced elevated levels of these two monokines was evaluated (Table I). None of the nine patients without salpingitis produced an elevated level of interleukin-1 or interleukin-6. In contrast, peripheral blood mononuclear

cells from three of the patients with salpingitis spontaneously produced elevated amounts of interleukin-1, and four produced elevated amounts of interleukin-6. Similar results were obtained with interferon gamma–stimulated cells (Table II). Four of the patients with salpingitis showed elevated interleukin-1 levels and three had elevated interleukin-6 production but none of the other women did so.

In contrast to the in vitro culture results, none of the sera from patients with salpingitis contained detectable tumor necrosis factor, interleukin-1, or interleukin-6.

Comment

Peripheral blood mononuclear cells from women with salpingitis readily released products of activated monocytes in vitro under conditions where the corresponding cells from women with other gynecologic disorders or from healthy women remained relatively quiescent. Under our experimental conditions, adherence of the monocytes to the culture dishes could have been a sufficient stimulus to activate the primed monocytes to release monokines.[11] In contrast, none of the patient's sera contained detectable levels of tumor necrosis factor, interleukin-1, or interleukin-6. This is consistent with reports demonstrating that tumor necrosis factor has a short half-life and is detectable in the circulation only for a short period of time at the onset of an infection.[12] Thus monokine production in vitro by unstimulated or interferon gamma–stimulated monocytes may be a more reliable indicator of infection than the presence of these compounds in serum.

Primed monocytes present in the circulation of women with salpingitis would be highly susceptible to activation in vivo at infected tubal sites, even at loci containing low concentrations of microorganisms. Primed monocytes can be activated by levels of bacteria that are insufficient to stimulate unprimed (resting) monocytes.[10] In addition, in cases of chlamydial salpingitis, nonproductive infections also may lead to the release of chlamydial antigens capable of activating monocytes.[6] Tumor necrosis factor has, in fact, been shown to induce the disordered synthesis of chlamydial antigens.[13] The resulting accumulation of monokines at specific sites would induce scarring and tissue damage. Furthermore, since tumor necrosis factor synergizes with bacterial endotoxin in the induction of tissue necrosis,[14] tumor necrosis factor production is most likely to initiate inflammatory tissue damage if a concomitant infection is also present.

C. trachomatis infections, even those causing severe tubal damage, are often accompanied by mild or no symptoms[15] and may therefore remain undetected. In addition, the standard antibiotic treatments may not always completely clear the organism from the female genital tract.[16] Therefore low-level infections, even by micrroorganisms not normally considered to be pathogenic, may become capable of inducing monokine secretion from monocytes that were primed by "silent" chlamydial tubal infections. This might especially be a problem during pregnancy. Many studies have now shown that products of activated monocytes can induce preterm pregnant complications.[17] The reported increased incidence of first-trimester spontaneous abortion,[18] preterm labor, or premature rupture of membranes[19, 20] in women with serologic or microbiologic evidence of *C. trachomatis* also may occur, at least partially, by this mechanism.

Salpingitis is certainly not the only infectious condition in which primed monocytes are present in the circulation. Monocytes from patients with pulmonary tuberculosis[21] or meningococcal meningitis[22] also were shown to be more responsive than monocytes from controls in releasing tumor necrosis factor. Acute localized infections at other body sites would be expected to produce similar findings. However, we have not observed primed monocytes in women with vaginal or urinary tract infections. This suggests that infections confined to mucosal surfaces may not prime circulating monocytes.

The presence of a chlamydial infection is often difficult to detect clinically or by culture techniques.[2, 23] The methods described in this report may therefore be of value in the evaluation of women with suspected salpingitis.

Maternal plasma level of endothelin is increased in preeclampsia

Alfredo Nova, MD,[a] Baha M. Sibai, MD,[a] John R. Barton, MD,[a] Brian M. Mercer, MD,[a] and Murray D. Mitchell, PhD[b]

Memphis, Tennessee, and Salt Lake City, Utah

Endothelin is a potent vasoconstrictor that is reportedly increased in conditions characterized by endothelial damage. Maternal plasma endothelin levels were compared between 27 women with preeclampsia (23 without and 4 with the hemolysis, elevated liver enzymes, and low platelet count syndrome) and 14 women with normotensive pregnancies. The mean ± SEM plasma endothelin values were significantly higher in patients with preeclampsia uncomplicated by the hemolysis, elevated liver enzymes, and low platelet count syndrome (5.48 ± 0.30 fmol/ml vs 3.86 ± 0.28, $p < 0.001$). In addition, the preeclamptic group with the hemolysis, elevated liver enzymes, and low platelet count syndrome had significantly higher endothelin levels than those without the syndrome (8.30 ± 1.62 fmol/ml vs 5.48 ± 0.30, $p < 0.05$). There was no correlation between plasma endothelin values and either systolic or diastolic blood pressure. We conclude that plasma endothelin levels are significantly increased in women with preeclampsia and particularly in those with the hemolysis, elevated liver enzymes, and low platelet count syndrome, suggesting an association with widespread endothelial damage. (AM J OBSTET GYNECOL 1991;165:724-7.)

Key words: Preeclampsia, endothelin, endothelial damage

There is increasing evidence that the vascular endothelium plays an important role in the regulation of vessel tone and regional blood flow.[1] Endothelin, a peptide discovered by Yanagisawa et al.[2] is produced and secreted in cultured endothelial cells and has been isolated from both porcine and human endothelial cells. Endothelin has potent vasoactive properties in vitro and is tenfold more potent than angiotensin II.[3] Plasma endothelin levels have been reported to be increased in patients with severe chronic hypertension, acute and chronic renal failure, and hemolytic uremic syndrome, implying that local endothelial cell injury may be associated with enhanced endothelin release.

Preeclampsia is characterized by vasospasm, reduced blood flow to various organs, and endothelial cell damage.[4, 5] Because endothelial cell injury and vasospasm are consistent findings in preeclampsia, we hypothesized that endothelium-derived substances such as endothelin may play a central role in the pathophysiology of preeclampsia. The purpose of this study is to compare plasma endothelin levels between patients with preeclampsia and a well-matched normotensive group.

Material and methods

The patients participating in this study were recruited from among those managed at the E.H. Crump Women's Hospital and Perinatal Center, University of Tennessee, Memphis. The study was approved by the Investigational Review Board Committee of the University of Tennessee, Memphis, and all patients gave informed consent for blood collection.

Inclusion and exclusion criteria were as follows: for the normotensive group, patients were included with a gestational age of 25 to 40 weeks, and excluded if they had any obstetric or medical complication of pregnancy and if in active labor. Patients with preeclampsia were excluded if they had other obstetric or medical complications of pregnancy and if in active labor. All patients had singleton pregnancies and none had any evidence of bleeding or fetal distress on admission.

Forty-one pregnant women between 25 and 40 weeks' gestation were studied; 14 were normotensive and 27 had preeclampsia-eclampsia. Twenty-two patients had severe preeclampsia, four had mild preeclampsia, and one had eclampsia. Four of the 22 with severe preeclampsia had the hemolysis, elevated liver functions, and low platelet count (HELLP) syndrome as defined by Sibai.[6] All patients with preeclampsia had persistent elevations in blood pressure of >140/90 mm Hg and 24 of the 27 had significant proteinuria (>300 mg/24 hour urine sample). None of the patients had prior history of chronic hypertension or renal disease.

Twelve of the normotensive women were nulliparous, whereas 24 of the 27 women with preeclampsia were nulliparous. Two of the three multiparous women had the HELLP syndrome; the other patient had eclampsia. Blood pressure was measured in a semirecumbent position with a standard mercury sphygmomanometer with an appropriate-sized cuff that was positioned at the level of the heart. Two blood pressure recordings were obtained immediately before blood collection. The average of these two recordings was used in the regression analysis of the endothelin levels.

Blood samples were obtained during either the antepartum period or the latent phase of labor in two normotensive patients and two patients with preeclampsia. Peripheral venous blood samples for endothelin were collected into chilled tubes containing 5 mg of ethylenediaminetetraacetic acid per milliliter and 500 U of aprotinin per milliliter. The plasma fraction was removed after immediate centrifugation at 4° C and subsequently stored at −70° C until assayed. At the same time, routine laboratory tests for preeclampsia, such as uric acid level, liver function, or coagulation studies were obtained with the same venipuncture.

Plasma endothelin concentrations were measured with a radioimmunoassay technique (Amersham Corporation, Arlington Heights, Ill.) after purification and concentration of plasma samples. Briefly, 3 ml of plasma were acidified and loaded into a small chromatography column (Sep Pak, C_{18}, Millipore Corporation, Millford, Mass.). The column was washed sequentially with (4%) acetic acid and distilled water before immunoreactive endothelin was eluted with methanol. Each sample in methanol was evaporated to dryness under a stream of nitrogen and the residue dissolved in 250 μl of assay buffer that was included in the kit. Duplicate 100 ml aliquots were taken for assay. The sensitivity of the assay (2 SD of zero-point binding) was 1.03 fmol. Intraassay and interassay coefficients of variation were 4.1% and 10.4%, respectively. The antiserum recognizes both endothelin 1 and endothelin 2.

Statistical analysis was done with analysis of variance or the Student t test where appropriate. Plasma endothelin levels were compared with the Mann-Whitney U test. A p value of <0.05 was considered significant.

Results

Table I summarizes the clinical findings among the normotensive women and those with preeclampsia with and without HELLP syndrome. There were no significant differences in maternal or gestational age at the time of blood sampling between the normotensive and preeclamptic groups.

Fig. 1 describes the plasma endothelin levels among the three groups of patients. Plasma endothelin levels were significantly higher in patients with preeclampsia without the HELLP syndrome than the levels in the normotensive group (5.48 ± 0.30 fmol/ml vs 3.86 ± 0.28, $p < 0.001$). In addition, patients with HELLP syndrome had significantly higher endothelin levels than did patients with preeclampsia without the HELLP syndrome (8.30 ± 1.62 fmol/ml vs 5.48 ± 0.30, $p < 0.05$).

Among the preeclamptic group, there was no correlation between maternal plasma endothelin values and systolic blood pressure, diastolic blood pressure, platelet count, uric acid, or serum glutamate oxaloacetate transaminase levels.

Comment

Endothelin 1 is a 21-residue vasoconstrictor peptide that has been isolated from the supernatant of porcine aortic endothelial cells.[2] It is one of a family of peptides that are produced in mammals, including humans. Endothelin 1 has a wide range of regulatory functions, particularly cardiovascular, renal, respiratory, and endocrine. Endothelin 1 also has a potent mitogenic ac-

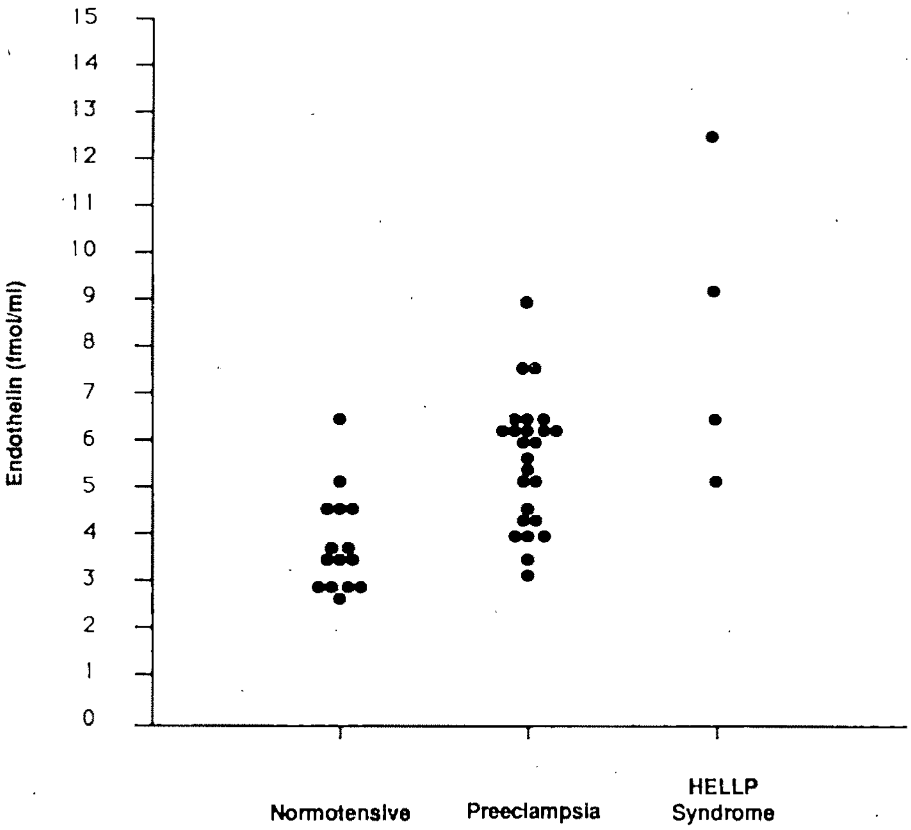

Fig. 1. Distribution of plasma endothelin levels among the three groups of patients. Preeclampsia versus normotensive ($p < 0.001$); preeclampsia versus HELLP syndrome ($p < 0.05$).

tivity on fibroblasts and smooth muscle cells.[1] The other family members, endothelin 2 and endothelin 3, have not been precisely characterized in their biologic activity. Only endothelin 1 has been recovered from endothelial cells. Endothelin 1 has a long-lasting vasopressor action, and it is tenfold more potent than angiotensin II, thus being the most potent vasoconstrictor yet identified.[3] The kidney is particularly sensitive to its vasoactive effects, which decrease both glomerular filtration rate and urine output.[7]

Increased plasma levels of endothelin 1 have been reported in several disease states characterized by endothelial damage and coagulopathy, such as hemolytic uremic syndrome, thrombotic thrombocytopenic purpura, and acute renal failure.[8] In addition, elevated maternal plasma levels of endothelin have been reported in preeclampsia.[9, 10] Kamoy et al.[9] reported elevated plasma levels of endothelin 1 in eight women with pregnancy-induced hypertension and lower plasma endothelin 1 levels in pregnancy compared with the nonpregnant state. Taylor et al.[10] reported elevated maternal plasma endothelin 1 in 10 preeclamptic patients at term; however, in patients who had serial blood sampling during pregnancy, plasma endothelin 1 levels were not increased before the clinical development of preeclampsia.

There is evidence of vascular endothelial injury in preeclampsia, both from ultrastructural studies[5] and from biochemical studies: increased fibronectin[11] as well as factor VIII antigen.[12] In addition, the increased fibronectin develop long before the clinical onset of the disease. Thus the endothelial response to injury may antedate and contribute to the occurrence of preeclampsia.

Our findings reveal a significant increase in plasma endothelin levels in patients with preeclampsia, particularly in those with the HELLP syndrome. Endothelial cell damage is believed to be widespread in these patients, with the resulting microangiopathy, platelet consumption, and disseminated intravascular coagulopathy. The endothelin levels in preeclampsia did not correlate with either maternal systolic or diastolic blood pressure values. However, endothelin levels correlated with the presence of HELLP syndrome. These findings suggest that endothelin 1, which is increased in conditions associated with endothelial damage, may be considered a marker of endothelial damage with pathophysiologic significance in preeclampsia.

Endothelial cells are capable of releasing a variety of local mediators such as prostacyclin, endothelium-derived relaxing factor, tissue plasminogen activator, fibronectin, heparan sulfate, platelet-activing factor, and endothelin 1.[1] Some of these mediators appear to exert a counterregulatory effect on each other. For example, the pressor effects of circulating endothelin are limited by the release of prostacyclin and endothelium-derived relaxing factor,[13] indicating that the potent and long-lasting pressor effect of endothelin is modulated by the endothelial release of potent vasodilating and antiaggregatory agents.

Under conditions of endothelial damage, such as preeclampsia, the increased endothelin 1 levels may lead to progressive vasospasm with eventual reduction in both renal plasma flow and uteroplacental blood flow. In addition, the increased endothelin 1 levels may be responsible for the increase in mitogenic activity reported in preeclampsia.[14]

In summary, endothelin is increased in patients with preeclampsia, particularly in those with HELLP syndrome. Further research on endothelin 1 and other related endothelial mediators such as prostacyclin and endothelium-derived relaxing factor may enable us to better understand the endothelial response to circulating injury in preeclampsia.

We wish to acknowledge Dr. Roberto Romero of Yale University and Dr. Umberto Bellati of the University of Chieti (Chieti, Italy) for their contributions to this study.

In utero fetal muscle biopsy for the diagnosis of Duchenne muscular dystrophy

Mark I. Evans, MD,[a] Anne Greb, MS,[a] Louis M. Kunkel, PhD,[b] Alan J. Sacks, MD,[a] Mark P. Johnson, MD,[a] Corinne Boehm, MS,[c] Haig H. Kazazian, Jr., MD,[c] and Eric P. Hoffman, PhD[b]

Deoxyribonucleic acid techniques can be used to diagnose Duchenne muscular dystrophy prenatally in male fetuses that are at risk. Deoxyribonucleic acid–based prenatal diagnosis can be impossible when there is only one prior affected male and there is no identifiable deletion or alteration. We performed fetal muscle biopsy in utero in such a case and documented the presence of dystrophin, thereby confirming normality in a male fetus at risk. This first in utero experience adds fetal muscle biopsy to the available procedures for fetal tissue diagnosis. (AM J OBSTET GYNECOL 1991;165:728-32.)

Key words: Duchenne muscular dystrophy, prenatal diagnosis, in utero muscle biopsy

Duchenne muscular dystrophy is a progressive, degenerative muscle disease that is inherited as an X-linked recessive trait. Affected boys have an unremarkble early childhood, with the first overt clinical symptoms appearing around 2 to 5 years of age. Most patients are confined to a wheelchair by the age of 10 and usually die by the age of 20. It is one of the more common genetic diseases among all populations of the world. Affecting approximately one in 3500 live-born male infants, Duchenne muscular dystrophy is caused by the deficiency of a minor component of muscle tissue, called dystrophin.[1-3] Dystrophin helps form the membrane cytoskeleton in normal muscle, and its deficiency results in myofiber necrosis, presumably because of membrane instability.

Approximately 70% of cases are inherited through a carrier mother, whereas 30% of cases show no previous family history and therefore represent de novo mutations of the dystrophin gene.[4] This high spontaneous mutation rate of the dystrophin gene may result from the enormous size of the gene, which is nearly an order of magnitude larger than all other genes studied to date.[5] This high occurrence rate of spontaneous mutations poses problems in genetic counseling. In those women with no prior family history and normal creatine kinase levels, a Bayesian probability of 30% for having future subsequent sons affected with Duchenne muscular dystrophy can be calculated.

The recent isolation of the dystrophin gene[6] and identification of its normal protein product[1] have prompted the advent of what has been called molecular diagnostics for this disorder.[7] Specifically, the actual gene mutation causing Duchenne muscular dystrophy can be identified in 65% of affected individuals as a gene deletion.[1] In these families female relatives carrying the same mutation can be identified. Prenatal diagnosis can then be offered by analyzing the deoxyribonucleic acid (DNA) isolated from chorionic villi or amniotic fluid cells for the presence or absence of the same deletion mutation that was identified in the affected family member.

However, in the remaining 35% of families who do not have deletion mutations, both carrier detection and prenatal diagnosis are more difficult and less accurate. In such cases, restriction fragment length polymorphism analyses must be undertaken in an attempt to mark the affected X chromosome in the family. If only a single affected family member exists, it is often impossible to determine whether the mother of the affected boy is a carrier. This uncertainty has ramifications not only for future pregnancies of the mother but also for the carrier risks of other at-risk female relatives. With Bayesian analysis only, the probability of being a carrier can be generated. If the male fetus at risk of being affected with Duchenne muscular dystrophy inherits an X chromosome from his mother that is different from the previously affected male, then, with the exception of the small possibility of crossing over in meiosis, the diagnosis of Duchenne muscular dystrophy can be excluded.[8] However, if the male fetus inherits the *same* X chromosome as his previously affected sib, the risk that the fetus is affected is the same

as the risk that the mother is, in fact, a carrier. Such uncertainty in risk assessment has been seen in other X-linked disorders, such as hemophilia.[9]

We describe such a genetically *difficult* family, where an unborn male fetus has inherited the same X chromosome as his brother who has Duchenne muscular dystrophy, has no dystrophin gene deletion, and apparently represents a sporadic case. Thus the risk that the fetus will have Duchenne muscular dystrophy is the same as the risk that the mother will be a carrier, which is approximately 30%. To avoid termination of this high-risk pregnancy, a novel method, namely, dystrophin protein testing of the fetal muscle in utero,[8] was performed and was diagnostic. As this was an innovative approach, this procedure was cleared with the department chairman and research committee, but a formal university institutional review board approval was not necessary for a single therapeutic attempt, given that fetal tissue biopsies are long-standing, accepted procedures. The procedure was not attempted on a patient seeking termination, for example, because that would violate federal regulations of pregnancy and require institutional review board approval. The operator (M.I.E.) felt competent on the basis of thousands of invasive procedures performed, as to the technical feasibility of the procedure. This first case of successful in utero muscle biopsy and the molecular diagnostic methods used are described in this report.

Case report

A 41-year-old white woman, gravida 4, para 2, spontaneous abortion 1 (Fig. 1, III 2), was referred to the Division of Reproductive Genetics at Hutzel Hospital–Wayne State University for genetic counseling and chorionic villus sampling because of advanced maternal age. However, analysis of the family history first revealed a 19-year-old son (IV1) with Duchenne muscular dystrophy with follow-up for many years by a Duchenne muscular dystrophy clinic. Further analysis of the family history revealed that he was the only family member affected with the disease. The proband also has an unaffected daughter. Her sister had two unaffected sons. The proband had creatine kinase levels determined on three occasions in the last 5 years, all of which fell within the normal range. At her initial visit at 9 weeks' gestation, she underwent chorionic villus sampling. Karyotype revealed a 46,XY chromosomally normal male. Blood was obtained for molec-

ular diagnosis and analyzed at The Johns Hopkins Hospital.

Although 65% of males with Duchenne muscular dystrophy have a dystrophin gene rearrangement, usually with a partial deletion causing them dystrophy, none of the major reported rearrangements were seen in the DNA of IV 1. Thus it was not possible by this type of analysis to determine whether the mother was a carrier and the fetus was at risk.

Restriction fragment length polymorphism haplotype analysis was undertaken to determine whether the male fetus of III 2 had inherited her at-risk haplotype. Analysis was informative at two restriction fragment length polymorphisms, an *Eco*RV site that was detectable with probe C-7 that flanks the gene on the 3′ side and an internal *Eco*RV site that was detected by the intragenic probe pERT 87-1. IV 1 and the fetus (IV 4) had inherited the same allele type at both of these markers (Table I). Thus the chance that the fetus was affected with Duchenne muscular dystrophy was approximately the same that III 2 was, in fact, a carrier. By Bayesian calculations, taking into account the family pedigree and the three normal creatine kinase results obtained on III 2, the chance that she was a carrier was calculated to be approximately 30%. Thus the chance that her fetus was affected with Duchenne muscular dystrophy also was approximately 30%.

The option of pregnancy termination followed by dystrophin analysis[1-3] and possible reattempted pregnancy was offered to the patient. However, she hoped for more information and did not want to risk aborting a normal male fetus. The option of attempting a fetal muscle biopsy was presented, and the patient gave informed consent for the innovative approach. The consent included our uncertainty of the likelihood of being successful and the unknown risks of the procedure.

Under ultrasonographic guidance at approximately 17 weeks 5 days' gestation, a Klear Kut (Baxter, Los Angeles) kidney forceps gun was inserted through a nick incision in the skin and into the uterine cavity. The choice of Klear Kut instrument was one of convenience because it is used routinely in our hospital. The Klear Kut device is useful in having a shearing, but specimen-protecting, feature necessary to assure that the specimen is not lost when the needle is removed from the uterus. Several other similar devices are available and have been used for similar procedure. The forceps was positioned for entry into the gluteal muscle in a downward fashion over the buttock (Fig. 2). The forceps was advanced inside the skin, and a core biopsy of muscle was obtained. The buttocks were thought to be easier to use than the calf because they are larger and less likely to move. By sampling on the outside and posteriorly, the risk of nerve injury can be reduced but certainly never eliminated. The specimen was then sent to Boston Childrens Hospital for dystrophin analysis. Unfortunately, the specimen was thought to be inadequate because of insufficient muscle tissue content as determined by Coomassie Brilliant Blue G staining of myosin heavy chain protein. The procedure was re-

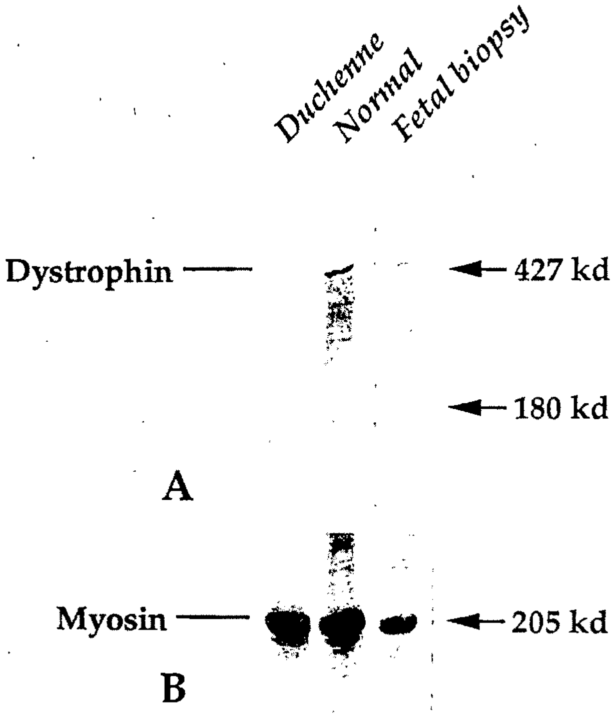

Fig. 3. Dystrophin immunoblot analysis of fetal biopsy. Shown is dystrophin analysis *(panel A)* and myosin heavy chain analysis *(panel B)* done sequentially on the same immunoblot. *Duchenne* lane contains total muscle protein from 5-year-old patient with Duchenne muscular dystrophy who has deletion encompassing his entire dystrophin gene. *Normal* lane contains muscle from normal adult. *Fetal biopsy* lane contains total solubilized protein from proband discussed in this report.

peated again at 19 weeks without difficulty; an adequate muscle specimen was obtained, and analysis of the biopsy for dystrophin content found a normal amount of the dystrophin protein, compared with control levels, indicating that the fetus was not affected with Duchenne muscular dystrophy (Fig. 3). Ironically, the 19-year-old son (IV 1) died of respiratory failure the next week after the diagnosis was made.

The remainder of the pregnancy was uneventful. At 40 weeks she was delivered of a 7 pound 15 ounce male infant with Apgar scores of 3 at 1 minute and 7 at 5 minutes. He was observed initially in the neonatal intensive care unit because of apneic spells, but he went home within 1 week with follow-up on an apnea monitor and has done well ever since. Examination of the buttocks revealed a small scar from the puncture site. Creatine kinase levels were within normal limits (44 IU/L) at 6 months of age.

Comment

Genetic analyses, by either deletion or linkage studies, are informative and accurate in the large majority of families. However, specific cases often arise whereby genetic analyses prove uninformative or inconclusive. Such situations often occur when the affected family member is not available for dystrophin gene analysis, or, as in the case reported here, if there is a sporadic case with no detectable gene deletion. In a previous report dystrophin testing of an at-risk abortus was successfully used to determine whether the proband was a carrier and to identify the Duchenne muscular dystrophy–carrying X chromosome.[8] Dystrophin testing of at-risk abortuses has been subsequently used successfully in many cases where DNA analysis has proved ambiguous (Hoffman EP. Unpublished observations).

Clearly, it is not an ideal situation if a pregnancy must be terminated to determine the maternal carrier status or whether the fetus is affected, or both. In the case presented here termination of an at-risk pregnancy was at least postponed in favor of in utero muscle biopsy. The muscle biopsy was successful and demonstrated that the fetus was, in fact, normal, even though it had inherited the same X chromosome as an affected sibling. Thus we were able to show that the affected individual in this family was indeed a sporadic case and that the mother was not a carrier of Duchenne muscular dystrophy, except for the small chance of gonadal mosaicism.

The development of invasive biopsy techniques for fetal tissues first began in the early 1980s, when fetoscopic blood sampling, skin biopsies, and liver biopsies were first attempted.[10] With the development of very sophisticated ultrasonographic technology, visualization of the fetus has superceded previous fiberoptic scope techniques. Thus most invasive procedures are now done with ultrasonographic guidance. Furthermore, the development of molecular techniques has obviated the need for tissue products in many cases, such as in ornithine transcarbamylase deficiency, which previously required a fetal liver biopsy.[11] Fetal tissue sampling for diagnosis will still be important, because in many disorders molecular approaches may not be available or measurement of gene products may be necessary to adequately diagnose or gauge the effectiveness of therapy. Whether 17 weeks is too early to have a reasonable chance of a successful biopsy is unclear. Further experience will be needed to evaluate the efficacy of the procedure and the optimum timing. Fortunately, only tiny quantities of muscle are needed for the laboratory analysis.

From this first successful experience, it is impossible to gauge accurately the risks of an in utero fetal muscle biopsy. It clearly would be preferable to do procedure-related DNA diagnoses of Duchenne muscular dystrophy from chorionic villus sampling or amniocentesis, because of both earlier gestational ages at which the procedures can be performed and their demonstrated safety. However, the development of the ability to do fetal muscle biopsies adds a second dimension beyond sex selection and Bayesian calculations to the procedures for diagnosis of such cases when DNA diagnosis is inconclusive or otherwise impractical.

Concentration of digoxin-like immunoreactive substance in patients with preeclampsia and its relation to severity of pregnancy-induced hypertension

Krzysztof Kaminski, MD, PhD, and Tomasz Rechberger, MD, PhD
Lublin, Poland

Digoxin-like immunoreactive substance (endoxin) was measured in pregnant patients with pregnancy-induced hypertension. The mean level was significantly higher than that in healthy control subjects ($p < 0.001$). Patients with eclampsia had a significantly higher concentration than did women with preeclampsia ($p < 0.03$). A positive significant correlation was found between concentration of digoxin-like immunoreactive substance and the value of the index of gestosis of von Goecke and Schwabe ($p < 0.03$). Analysis of patterns during various kinds of therapy revealed that nitrendipine was most effective in lowering endoxin concentration. Although an insignificant correlation was found between maternal concentration and both birth and placental weights, the compartmental differences observed seem to suggest fetoplacental origin of this substance. (Am J Obstet Gynecol 1991;165:733-6.)

Key words: Digoxin-like immunoreactive substance, endoxin, pregnancy-induced hypertension, antihypertensive treatment

Preeclampsia complicates 5% to 7% of all pregnancies and is associated with increased risk for both mother and newborn. The precise cause of pregnancy-induced hypertension remains obscure; a variety of cofactors are being considered.[1-7] During the last decade much attention has been paid to natriuretic substances such as atrial natriuretic factor and digoxin-like immunoreactive substance, and their role in water and sodium retention has been studied.[8-11]

The aim of this study was to test the relationship between the digoxin-like immunoreactive substance serum concentration in patients with preeclampsia and the severity of the pregnancy-induced hypertension syndrome. Additionally, the influence of various modes of pharmacologic therapy on serum digoxin-like immunoreactive substance patterns was investigated.

Material and methods

The 85 patients enrolled in the study were divided into five groups (Table I). The control group ($n = 45$) consisted of nonpregnant healthy subjects and pregnant women with uncomplicated pregnancies. The study group consisted of 40 patients with pregnancy-induced hypertension in the third trimester. Patients with chronic renal disease, essential hypertension, or liver disfunction and those receiving digitalis glycosides were excluded from the study. Diagnosis of preeclampsia was based on the criteria established by the Committee on Terminology of the American College of Obstetricians and Gynecologists.[12] The severity of pregnancy-induced hypertension was calculated according to the index of gestosis of von Goecke and Schwabe[13] (Table II). Gestational age was determined by means of the last menstrual period and physical examination and was confirmed by ultrasonographic biometry.

Patients with preeclampsia were randomly divided into three groups according to the mode of treatment: 11 patients receiving nitrendipine, 20 mg four times daily, 23 patients receiving dihydralazine, 25 mg six times daily and six patients treated with continuous intravenous infusion of 50 mg Largactil, 50 mg diphenhydramine hydrochloride, and 100 mg of meperidine hydrochloride in 500 ml of 5% dextrose. Three determinations of maternal concentration of digoxin-like immunoreactive substance were made: after 24 hours of bed rest and before medication, after 3 days of therapy, and immediately after delivery. The interval between the second and third estimation varied from 5 to 14 days. In 15 cases digoxin-like immunoreactive substance concentrations were estimated in the umbilical cord vein and in the newborn serum within 24 hours post partum and correlated with birth and placental weights (Table III). Digoxin-like immunoreactive substance concentrations were estimated after serum deproteinization with a mixture of 5-sulfosalicilic acid and 50% methanol in equal parts by means of the fluorescence polarization immunoassay method with

the Abbott TDx system II (Abbott Diagn. Inc., North Chicago). The lower limit of assay sensitivity was 0.2 ng/ml. Concentrations of digoxin-like immunoreactive substance below this value were considered immeasurable. The statistical analysis was performed with the Student t test after homogeneity of variances was ascertained and by means of the Pearson correlation coefficient. A p value <0.05 was considered statistically significant.

Results

Digoxin-like immunoreactive substance concentrations in healthy nonpregnant women and healthy pregnant women in the first and second trimesters were immeasurable. Pregnant women with an uncomplicated course of gestation in the third trimester had mean concentrations that were more than twice as low as those found in patients with preeclampsia in the same stage of pregnancy (Table I). Furthermore, when we divided patients with pregnancy-induced hypertension into two subgroups, preeclamptic and eclamptic, we found that in the latter group the digoxin-like immunoreactive substance concentration was much higher (0.83 ± 0.29 ng/ml) than that seen in the first subgroup (0.56 ± 0.21 ng/ml), and this difference was statistically significant ($p < 0.03$) (Fig. 1). The severity

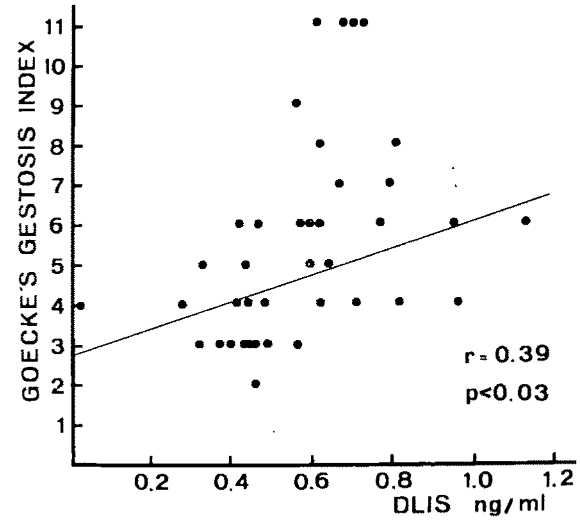

Fig. 2. Correlation between severity of pregnancy-induced hypertension measured as index of gestosis of von Goecke and Schwabe and maternal digoxin-like immunoreactive substance concentration.

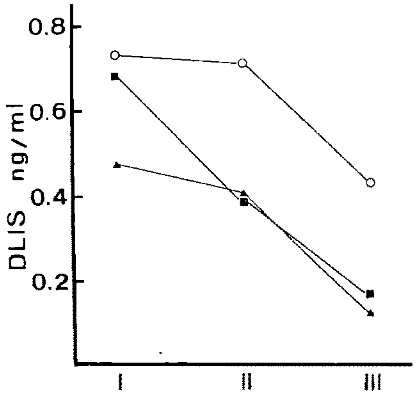

Fig. 3. Digoxin-like immunoreactive substance patterns during various kind of therapy. *Open circles,* Patients treated with Largactil + diphenhydramine hydrochloride + meperidine hydrochloride; *squares,* patients treated with nitrendipine; *triangles,* patients treated with dihydralazine. *I, II, III,* intervals between follow-up of digoxin-like immunoreactive substance estimations.

of pregnancy-induced hypertensive syndrome in our preeclampsic patients, measured as von Goecke and Schwabe's index of gestosis, was correlated with the serum digoxin-like immunoreactive substance concentration (Fig. 2). The statistical analysis of serum digoxin-like immunoreactive substance concentrations seen during the course of various kinds of therapy revealed that nitrendipine was most effective in lowering levels of the substance in the group of preeclamptic patients (Fig. 3). In the preeclamptic patients a positive correlation was found between digoxin-like immunoreactive substance concentration in cord blood serum and newborn venous blood in the first day of life, whereas such a correlation was not present in the group of healthy women. In both investigated groups we were unable to show any correlations between serum digoxin-like immunoreactive substance concentrations and newborn or placenta weights (Table III).

Comment

Digoxin-like immunoreactive substance was found in serum, urine, amniotic fluid, and placental homogenate with advancing pregnancy.[10, 11, 15] Gusdon et al.[16] and Valdes[10] have found significantly higher concentrations of digoxin-like immunoreactive substance in the serum of preeclamptic women, whereas Gonzalez et al.[17] and Phelps et al.[18] did not confirm these observations. Probably the discrepancies found in previously published data might be explained at least partially by the various analytic methods used, as shown by Pudek et al.[19] In our material we confirmed observations of the previously mentioned authors[10, 16] that digoxin-like immunoreactive substance concentration was significantly higher in groups of preeclamptic patients. Moreover, eclamptic patients had even higher levels than were found in preeclamptic women. The positive significant correlations between digoxin-like immunoreactive substance concentration and severity of the pregnancy-induced hypertensive syndrome, measured as the index of gestosis of von Goecke, that we found might suggest that this substance(s) is somehow involved in the pathogenesis of preeclampsia, most probably by the influence on membrane sodium-potassium-adenosine triphosphatase activity. To our knowledge this is the first report showing such a correlation in patients with pregnancy-induced hypertension. Goodlin[11] reported no detectable endoxin level in cord blood samples of anencephalic newborns and showed that bethamethasone therapy decreased the concentration of this substance; this might support the fetal adrenal origin of endoxin. In every case in our material endoxin concentration after delivery was markedly decreased in the manner reported previously by Gusdon et al.[16] confirming fetal origin of this particular substance(s). Endoxin has been proposed as an inhibitor of sodium, potassium, and calcium exchange and therefore as a peripheral vasoconstrictor agent.[20] Although several treatment regimens have been proposed for pregnancy-induced hypertension syndrome, no consideration has been given to maternal endoxin concentration. When we related modes of pharmacologic treatment to digoxin-like immunoreactive substance concentration pattern during therapy, we found that the calcium channel blocker nitrendipine was not only effective as a hypotensive agent but also the most effective in lowering the serum concentration of digoxin-like immunoreactive substance in preeclamptic patients. Because we found correlation between levels of digoxin-like immunoreactive substance in the cord and venous blood of newborns of preeclamptic patients and because such a correlation was not present when maternal digoxin-like immunoreactive substance concentrations were taken into consideration, we assumed that this factor (or factors) was of fetal origin. A special question is that concerning biologic activity of digoxin-like immunoreactive substance in humans during pregnancy complicated by pregnancy-induced hypertension and how we can influence sodium-potassium-adenosine triphosphatase membrane transport by direct manipulation of endoxin concentration. In one published case[21] a patient with eclampsia was treated with a specific antidigoxin antibody (Digibind), and reduction of digoxin-like immunoreactive substance concentration accompanied by antihypertensive effect was obtained.

Our results have shown that the severity of pregnancy-induced hypertension syndrome positively correlates with the maternal serum concentration of digoxin-like immunoreactive substance. Therefore the level of this substance might be of importance as an indicator of antihypertensive treatment effectiveness in preeclamptic patients.

A new proline aminopeptidase assay for diagnosis of bacterial vaginosis

Judith N. Schoonmaker, PhD,[a, b] **Brenda D. Lunt, MS,**[b] **David W. Lawellin, PhD,**[b]

Denver, Colorado, and Seattle, Washington

Bacterial vaginosis is one of the most common occurring vaginal conditions among women of reproductive age. A rapid and reliable laboratory test for diagnosis of bacterial vaginosis would be helpful in the clinical detection of this disease. Elevated proline aminopeptidase activity has been identified as a reliable marker enzyme for bacterial vaginosis. A proline aminopeptidase assay has been shown to predict accurately women with a clinical diagnosis of bacterial vaginosis. However, this assay has significant practical disadvantages, the most notable of which is the production of a carcinogenic end product, α-naphthylamine. We have developed a modified assay for this bacterial vaginosis marker enzyme with L-proline *p*-nitroanilide, a substrate that does not yield a carcinogenic end-product. The new proline aminopeptidase assay is a one-step test that is analyzed colorimetrically with microsomal leucine aminopeptidase used as a standard enzyme (linear from 3 to 125 mU per well). We have determined the activity of proline aminopeptidase in vaginal wet preparations from 57 patients with both assay methods. In addition, vaginal smears were examined with Gram's stain and analyzed for bacterial vaginosis with the Spiegel method. When compared with the Spiegel method, the two proline aminopeptidase assay methods were similar with respect to assay sensitivity (93%), specificity (91% to 93%), and the predictive value of a positive result (78% to 82%) or a negative result (97% to 98%). Vaginal wash samples also were assessed for proline aminopeptidase activity. Values for samples identified as bacterial vaginosis positive were significantly different ($p < 0.0001$) from those that were negative according to the Spiegel analysis of Gram's stain: negative results, 66 ± 41 mU/ml; positive results, 704 ± 145 mU/ml. These findings indicate that this improved proline aminopeptidase assay will offer a rapid, sensitive, and objective laboratory method for the diagnosis of bacterial vaginosis. (AM J OBSTET GYNECOL 1991;165:737-42.)

Key words: Bacterial vaginosis, nonspecific vaginitis, microbiology of the vagina, anaerobic bacteria

Bacterial vaginosis is one of the most common vaginal conditions in reproductive age women.[1] It accounts for approximately one third of all cases of vaginitis in women of reproductive age and is one of the most frequent complaints of women who visit their primary care physician. Bacterial vaginosis has been implicated in several gynecologic diseases and disorders, including recurrent urinary tract infections,[3] adnexal tenderness,[4] postpartum endometritis,[5] and increased risk of infection after gynecologic surgery.[6] In addition, the consistent and persistent association of bacterial vaginosis with placental infection, intraamniotic infection, preterm labor, premature rupture of membranes, and low birth weight[7-11] underscores the importance of developing a suitable diagnostic tool for the early detection and treatment of this vaginal condition. Devising a rapid and sensitive diagnostic test to confirm a diagnosis of bacterial vaginosis would facilitate objective and reliable detection of this condition. Such a test would also enhance the ability to study both putative complications of bacterial vaginosis and new treatment initiatives for this condition. The ideal test for bacterial vaginosis would have only a few simple steps, require no special equipment, have good assay sensitivity, specificity, and predictive value, and would be available commercially at a reasonable price.

Bacterial vaginosis is characterized by several changes in the normal microecologic and physicochemical environments of the vagina. This shift in vaginal flora from a predominance of *Lactobacillus* morphotypes to an overgrowth of anaerobic bacteria yields the production of bacterial metabolites that are unique to the vaginal fluid of women with bacterial vaginosis.[12] These factors have provided the basis for several methods of diagnosis of bacterial vaginosis. Clinical diagnosis of bacterial vaginosis, which is based on an evaluation of vaginal fluid and pH, has been difficult to standardize.

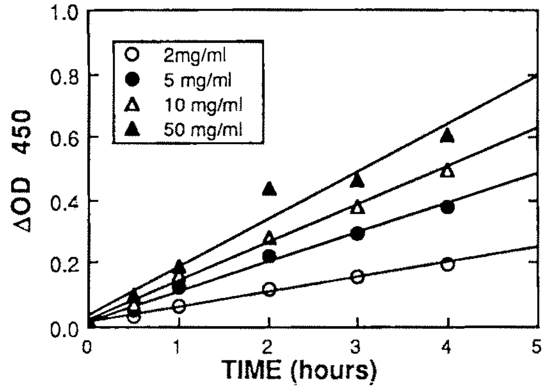

Fig. 1. Effect of increasing concentration of L-proline *p*-nitroanilide in proline aminopeptidase assay. Substrate concentration was increased from 2 to 5, 10, or 50 mg/ml. Reaction was initiated by addition of 62.5 mU of leucine aminopeptidase to each well. Assay was incubated at 37° C. Sample absorbances were read at 450 nm at 0.5, 1, 2, 3, and 4 hours.

The clinical parameters evaluated are somewhat subjective and vary with the adequacy of the specimen and the skill of the practitioner. The clinical diagnosis also may be ambiguous, as a result of multiple infections, menstruation, large amounts of cervical mucus, recent douching, or sexual intercourse before a pelvic examination.

Four laboratory methods also have been used to diagnose bacterial vaginosis: (1) culture of vaginal fluid for *Gardnerella vaginalis*,[13] (2) gas-liquid chromatographic analysis of vaginal fluid fatty acids[14, 15] and amines[16, 17] that are believed to be products of anaerobic bacterial growth, (3) Gram's stained vaginal smears that are read microscopically for bacterial morphotypes,[18, 19] and (4) assay for proline aminopeptidase (Enzyme Commission 3.4.11), a marker enzyme that is present in vaginal secretions and reliably elevated in bacterial vaginosis.[20]

In this study we sought to improve the proline aminopeptidase assay by eliminating some of the practical disadvantages inherent in the original assay design.[20] The substrate L-proline β-naphthylamide, when cleaved by proline aminopeptidase, yields the highly carcinogenic end product β-naphthylamine[21]; the assay reaction requires the secondary addition of a dye to visualize this end product. Finally, as published,[20] this test is purely qualitative; no standard reaction curves with β-naphthylamide were available for quantitation of the end product. The aims of this study were to develop a quantitative proline aminopeptidase assay with a substrate that does not yield a carcinogenic end product and to compare this new proline aminopeptidase assay with that of Thomason et al.[20] and with the standardized Gram's stain method of Spiegel et al.[19]

Material and methods

Samples were obtained from women enrolled in a larger study of lower genital tract microorganisms and prematurity.[22] A detailed history and physical examination were obtained from consenting women who were between 26 and 30 weeks' gestation. During speculum examination, samples of vaginal fluid were obtained from the midvaginal lateral wall with sterile cotton swabs. One swab was rolled onto a glass slide, and the sample was allowed to air dry for Gram's stain and evaluation for the presence of bacterial vaginosis. A second cotton swab saturated with vaginal fluid was placed in 1 ml of sterile Dulbecco's buffered saline solution. This vaginal "wet prep" was evaluated microscopically for motile trichomonads and yeast pseudohyphae, then frozen at −70° C for analysis with the proline aminopeptidase assay. Finally, the posterior vaginal fornix was irrigated with 4 ml of sterile Dulbecco's buffered saline solution. After standardized mixing, saline solution containing vaginal fluid was aspirated into a sterile syringe. These vaginal wash specimens were held initially at 4° C and frozen at −70° C within 4 hours of collection.

Vaginal smears were evaluated for bacterial vaginosis by a single investigator (S.L.H.), without knowledge of other findings, using the criteria established by Spiegel et al.[19] Vaginal smears were determined to be consistent with the presence of bacterial vaginosis on the basis of two criteria: (1) five or fewer *Lactobacillus* morphotypes per oil field and (2) more than five *G. vaginalis* morphotypes plus one other bacterial morphotype (gram-positive cocci, *Bacteroides* morphotypes, or curved rods). Analyses were scored as either positive or negative for bacterial vaginosis.

All chemicals used in the proline aminopeptidase assay were obtained from Sigma Chemical Company (St. Louis). When they had thawed, vaginal "wet prep" samples were centrifuged at 1000 *g* for 15 minutes to obtain a cell pellet. All but 100 μl of the supernatant was decanted, and the cell pellet was resuspended in the remaining supernatant. This suspension was then transferred to a microtiter plate well containing 50 μl of a 2 mg/ml solution in pH 7.0 Tris buffer of either L-proline β-naphthylamide (Thomason substrate) or L-proline *p*-nitroanilide (new substrate). After a 4-hour incubation at 37° C, fast garnet GBC dye was added to each well in the Thomason assay. After a second incubation for 5 minutes at room temperature, this assay was read visually.[20] A salmon red–pink color indicated a diagnosis of bacterial vaginosis. An orange-yellow color was scored negative for bacterial vaginosis. In the new proline aminopeptidase assay, samples were read visually immediately after the 4-hour incubation. A yellow color indicated a diagnosis of bacterial vaginosis; a

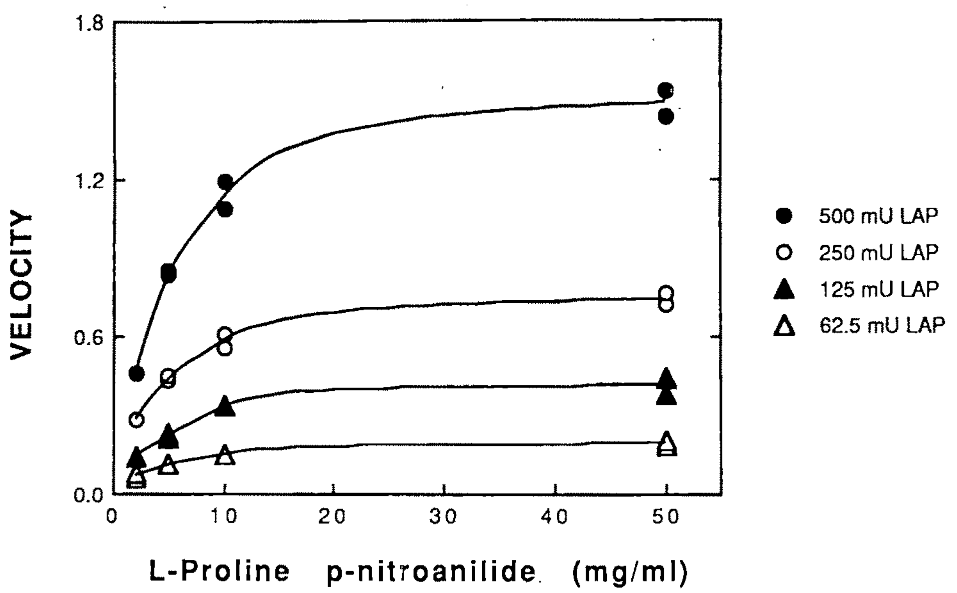

Fig. 2. Reaction velocity at 30 minutes as a function of substrate concentration. Increasing amounts of the substrate L-proline *p*-nitroanilide (2, 5, 10, and 50 mg/ml) were incubated with leucine aminopeptidase (62.5 to 500 mU per well). Sample absorbances (450 nm) were read after a 30-minute incubation at 37° C.

clear color was scored as negative for bacterial vaginosis.

Vaginal wash samples obtained from these patients also were analyzed for proline aminopeptidase activity. Before processing, 0.6 ml of each vaginal wash sample was centrifuged to obtain a cell pellet, and fluid in excess of 0.3 ml was discarded. The remaining 0.3 ml of fluid and cells were resuspended, and 0.1 ml aliquots were pipetted into microtiter plate wells; this allowed the determination of proline aminopeptidase activity in triplicate for each sample. Proline aminopeptidase activity was assessed quantitatively in these vaginal wash samples according to the new assay protocol. Use of L-proline *p*-nitroanilide as the chromogenic substrate allowed spectrophotometric quantitation of the assay end products. The presence of the yellow end product, nitroanilide, was measured spectrophotometrically at 450 nm. Because a standard preparation of proline aminopeptidase is not available, a standard curve was constructed for quantitative analysis with the use of microsomal leucine aminopeptidase (Enzyme Commission 3.4.11.1). This enzyme is specific for the amino terminal of peptides and will cleave proline from the substrate L-proline *p*-nitroanilide in a linear fashion from 3 to 125 mU/well. One unit of leucine aminopeptidase activity was presumed to be equal to 1 U of proline aminopeptidase. Under the standard conditions described, the assay limit of detection (defined as twice the assay background) was 0.02 U of absorption at 450 nm.

Assay sensitivity and specificity were calculated for each assay, with the Spiegel Gram's stain score used as the "gold standard" point of reference. Student's *t* test was used for statistical comparison of vaginal wash sample values.

Results

The kinetics of the enzyme-substrate reaction are shown in Figs. 1 and 2. The appearance of end product over time was examined for substrate concentrations ranging from 2 to 50 mg/ml (Fig. 2). The yellow-colored end product, nitroanilide, increased linearly (as evidenced by the increase of sample optical density at 450 nm) as a function of time, indicating that the reaction was run under conditions of substrate excess during the reaction time examined. Increased substrate concentration (up to 10 mg/ml) was beneficial in terms of the assay sensitivity; a deeper yellow color was apparent earlier in the incubation. A substrate concentration of 50 mg/ml yielded a high background that diminished assay sensitivity. Reaction velocity at 30 minutes is plotted as a function of substrate concentration in Fig. 2. At a substrate concentration of ≥10 mg/ml, the reaction velocity was at its maximum.

All clinical data described here were generated under the standard assay conditions of 2 mg/ml substrate incubated with the vaginal sample for 4 hours at 37° C. Table I shows the comparison of Gram's stain analysis and the two proline aminopeptidase assays that were run under standard conditions. A total of 57 vaginal samples were examined. Gram's stain analysis indicated that 42 samples were negative for bacterial vaginosis

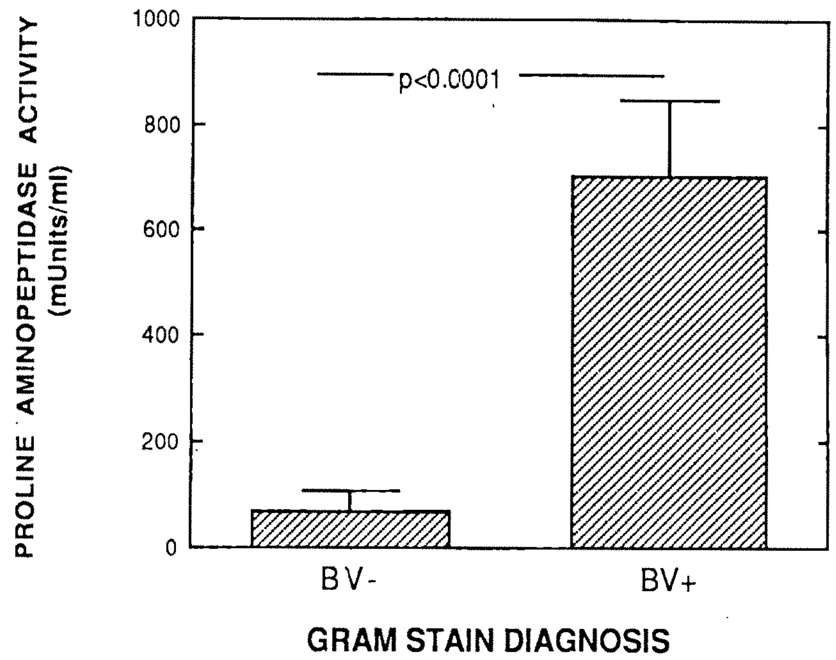

Fig. 3. Proline aminopeptidase activity (mean ± SE, milliunits per milliliter) in vaginal wash samples. Values from 57 vaginal samples are grouped according to Spiegel Gram's stain analysis.

Table I. Comparison of diagnosis: Gram's stain versus proline aminopeptidase assays

Method	*Diagnosis of bacterial vaginosis*	
	Positive	*Negative*
Gram's stain	42	15
Proline aminopeptidase assay		
L-Proline β-naphthylamide	39	18
L-Proline *p*-nitroanilide	40	17

and 15 were positive. The diagnoses that were based on the two proline aminopeptidase assays were remarkably similar, 39 and 40 were negative for bacterial vaginosis and 17 and 18 were positive for bacterial vaginosis. When compared with the Gram's stain results, proline aminopeptidase assay sensitivity was 93% and specificity was 91% to 93%.

Proline aminopeptidase activity was significantly elevated in vaginal wash samples obtained from women with bacterial vaginosis as determined by Gram's stain (Fig. 3; $p < 0.0001$, unpaired t test). The activity (mean ± SE) associated with bacterial vaginosis was 704 ± 145 mU/ml ($n = 15$). Absence of bacterial vaginosis was associated with a very low level of proline aminopeptidase activity (mean ± SE, 66 ± 41 mU/ml, $n = 42$).

Comment

These data demonstrate that the two proline aminopeptidase assay substrates examined, L-proline β-naphthylamide and L-proline *p*-nitroanilide, yield similar results with respect to a diagnosis of bacterial vaginosis. When compared with the results of Gram's stain, both proline aminopeptidase assays yielded similar findings. The proline aminopeptidase assay sensitivity (93%) was well within the range of acceptable values for a reliable diagnostic test. Assay specificity was also acceptable at 91% to 93%. The revised proline aminopeptidase assay offers noncarcinogenic substrate, L-proline *p*-nitroanilide.

This new proline aminopeptidase assay also has the capacity for quantitation of vaginal proline aminopeptidase activity. Our data show that activity of this enzyme was significantly elevated in women with bacterial vaginosis, as determined by Gram's stain analysis. There was, however, some variability apparent in proline aminopeptidase activity present in vaginal wash samples that may be attributed to the variability inherent in this sampling method. Vaginal fluids are variably diluted, depending on the amount of fluid present before introduction of saline solution into vagina. Also, the recovery of saline solution and fluid removed from the vagina is difficult to standardize.

In the report of Thomason et al.,[20] proline aminopeptidase in vaginal fluid correlated well with a positive clinical diagnosis of bacterial vaginosis. In our hands there is also an excellent correlation between diagnosis of bacterial vaginosis by Gram's stain and the presence of proline aminopeptidase, whether the assays employed proline β-naphthylamide or L-proline *p*-nitroanilide. Although it has not yet been carefully investigated, proline aminopeptidase is presumed to be a product of the bacteria associated with bacterial vaginosis. Mobiluncus and *G. vaginalis* have been shown to produce proline aminopeptidase (Hillier SL. Unpublished data). Other genera known to produce proline aminopeptidase include *Actinomyces*, *Streptococcus* (viridans streptococci), and *Peptostreptococcus*.[23] Additional work is needed to identify the specific organism(s) responsible for the synthesis of this enzyme in the setting of bacterial vaginosis. In addition, the vaginal conditions that are specific to bacterial vaginosis and are conducive to production and secretion of this marker enzyme remain to be determined.

Several important advantages of the modified assay for proline aminopeptidase serve to recommend it as an outstanding candidate for further use and validation in the clinical setting. Use of L-proline *p*-nitroanilide provides a simple one-step assay; vaginal fluid can be placed directly into a well containing the substrate. This assay is relatively rapid; it can be completed within 4 hours. The assay is objective; a positive or negative diagnosis can be determined visually or, if the equipment is available, spectrophotometrically.

Clinical diagnosis of bacterial vaginosis is currently widely used; it includes an assessment of the appearance of the vaginal fluid, determination of pH, detection of an amine odor, and microscopic examination of a wet mount of vaginal fluid. Unfortunately, the necessary equipment and expertise are not always available to clinicians. Thus access to simple laboratory methods for the diagnosis of bacterial vaginosis would be valuable.

Several laboratory analyses have been used to detect metabolites associated with bacterial vaginosis and to confirm a clinical diagnosis of bacterial vaginosis.[15-17, 20] These methods, however, require expensive equipment and reagents not easily available to clinicians.

Microscopic examination of Gram's stained vaginal smears has proved practical and economical. Diagnosis of bacterial vaginosis by Gram's stain criteria has been shown to be superior to diagnosis that is based on vaginal cultures in both pregnant and nonpregnant women.[12, 14, 19, 24] However, the subjectivity and dependence on investigator skill that are inherent to the Gram's stain analysis[24] suggest the need for a more objective method for the diagnosis of bacterial vaginosis.

The isolation of *G. vaginalis* also has been examined as a predictor of bacterial vaginosis. *G. vaginalis* can be recovered from 83% to 94% of women with clinical signs of bacterial vaginosis.[12] The presence of *G. vaginalis*, however, is not restricted to women with bacterial vaginosis.[1, 4, 12, 14] Accordingly, while the isolation of *G. vaginalis* has high sensitivity, it has low specificity and low predictive value of a positive culture. Krohn et al.[12] reported the consistent association of bacterial vaginosis with increased isolation of *G. vaginalis, Bacteroides* spp., and *Mycoplasma hominis* and with decreased isolation of facultative lactobacilli. Although this microbial pattern appears to be a good predictor of bacterial vaginosis, the microbiologic methods for culture and identification of these bacteria are time-consuming and costly and require a degree of expertise that is not universally available.

In spite of the currently available methods for diagnosis of bacterial vaginosis, there clearly remains a need for a quick, easy, and objective method to confirm a clinical diagnosis of bacterial vaginosis. The optimum means of screening for the presence of bacterial vaginosis remains to be determined. Both proline aminopeptidase assays offer rapid, easy, and objective means for the diagnosis of bacterial vaginosis. Although the number of samples analyzed in this study is limited, our findings suggest that further clinical validation of this new proline aminopeptidase assay is worthwhile.

Pemphigus gestationis (herpes gestationis): A case report

Igal Wolman, MD,[a] Joseph Ophir, MD,[b] David Pauzner, MD,[a] Sarah Brenner, MD,[b] and Menachem P. David, MD[a]

Tel Aviv, Israel

Pemphigus gestationis is a rare disease, probably of immunologic origin, that causes the placenta to absorb immunoglobulins and deposit them in its basement membrane. The resulting placental insufficiency leads to increased morbidity and mortality among the offspring of such patients. A case of pemphigus gestationis is presented, and the importance of early diagnosis is discussed. (AM J OBSTET GYNECOL 1991;165:743-4.)

Key words: Pemphigus gestationis

Pemphigus gestationis is a rare disease unrelated to any known viral infection. Its incidence has been roughly estimated to be 1 in 10,000 deliveries. The disease is probably of immunologic origin and consists of pruritic, polymorphic, inflammatory, subepidermal bullous dermatosis of pregnancy and the puerperium. The following is a report of a case of pemphigus gestationis, its workup, and its treatment during pregnancy.

Case report

A 26-year-old, gravida 2, para 1 woman was admitted to the dermatologic ward at 28 weeks' gestation. Her medical history and course of pregnancy until admission had been uneventful. At 27 weeks' gestation she began to notice what she described as mosquito bites located around the umbilicus and on the right foot.

On admission she had a highly pruritic papulovesicular eruption that involved the abdomen, legs, and soles. Later the hands and face were involved, as well. The lesions varied from erythematous, edematous papules to large bullae with different intermediate forms (Fig. 1). A biopsy of the perilesional area was performed and pemphigus gestationis was diagnosed by means of histopathologic examination and direct immunofluorescence.

Treatment with 20 mg per day of cortisone taken by mouth was immediately initiated, without any apparent response. When dosage was increased to 60 mg per day of cortisone, she responded well. Special attention was given to the fetal growth pattern, which was measured by serial ultrasonographic examination. Flow examination results were within the normal range, biweekly nonstress test results were reactive, and growth pattern was normal.

At 35 weeks' gestation the patient had regular uterine contractions and was delivered of a live male infant weighing 2850 gm with Apgar scores of 10 at 1 minute and 10 at 5 minutes. The weight of the placenta was 580 gm. A biopsy performed on a sample taken from the placenta did not reveal deposits of the third component of complement (C3) in the basement membrane.

The patient was rehospitalized immediately post partum because of a severe exacerbation and again was successfully treated with cortisone and antihistamines. Human leukocyte (HLA) antigen typing was performed, and the patient was found to have a phenotype of A1, A30, B35, B5, Cw4, DR3.

The infant had a similar eruption that subsided within weeks without special treatment.

Comment

Although rare, the two most common types of bullous dermatosis in pregnancy are pruritic urticarial papules and plaques of pregnancy and pemphigus gestationis.

The exact cause of pemphigus gestationis is unknown, but the consistent finding of C3 deposits at the basement membrane zone of lesional and normal-appearing skin, along with the findings of an avid component-fixing immunoglobulin G antibody in the serum, implies a role for immunologic mechanisms. A genetic predisposition has also been proposed for patients in the HLA-B8, DR3, and DR4 phenotypes.

When physicians are confronted with bullous dermatosis, it is essential to differentiate pemphigus gestationis from pruritic urticarial papules and plaques of pregnancy. In contrast to pruritic urticarial papules and plaques of pregnancy, which does not seem to recur in subsequent pregnancies and does not increase fetal morbidity, there is a great increase in the number of small newborns and in infant mortality among the offspring of mothers with pemphigus gestationis.[1]

6/1/30374

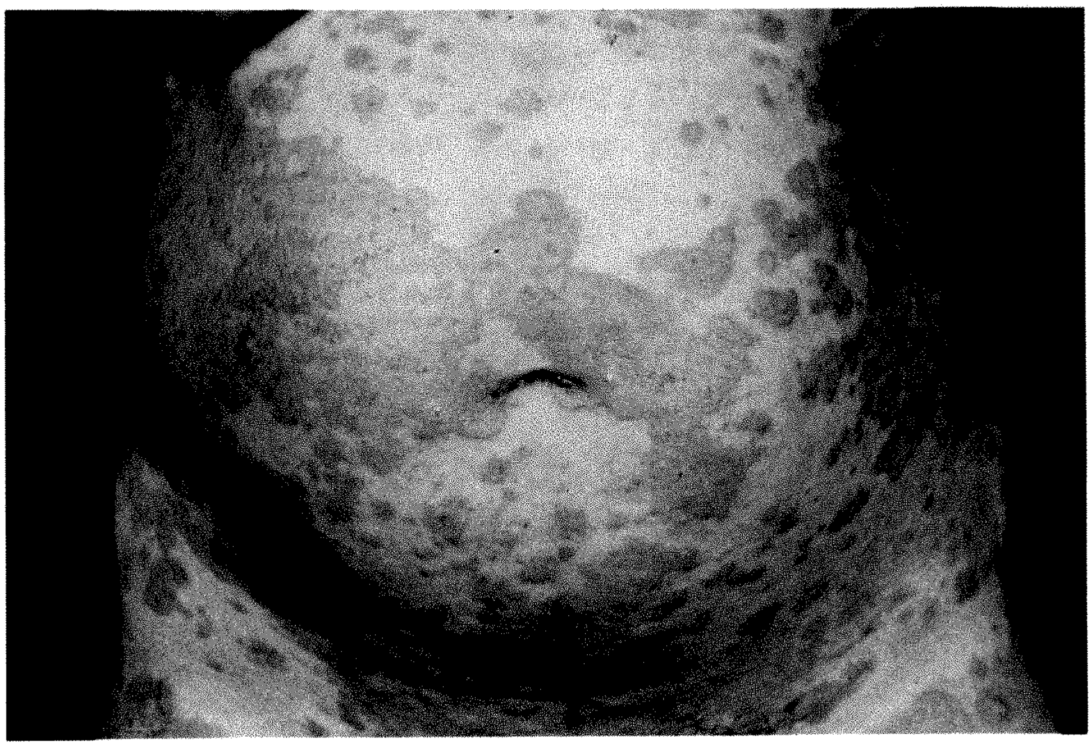

Fig. 1. Papulovesicular eruption on abdomen and flanks of woman with pemphigus gestationis at 28 weeks' gestation.

Direct immunofluorescence studies of the peribullous and urticarial lesions or of normal-appearing skin demonstrate heavy homogeneous liner deposition of C3 along the basement membrane zone with concomitant immunoglobulin G deposits in 30% to 40% of patients.

Indirect immunofluorescence assay showed the sera of patients with pemphigus gestationis to contain an antibody that avidly binds complement to the basement membrane of normal skin (pemphigus gestationis factor).

The fetus remains relatively protected from the immune complex formation because the placenta absorbs the immunoglobulin and deposits it within the placental basement membrane.[2] This phenomenon results in an increased frequency of placental insufficiency, which causes increased morbidity and mortality in the offspring of patients with pemphigus gestationis.

The treatment of pemphigus gestationis consists of systemic corticosteroid administration, which is usually quite effective in relieving the pruritus and in suppressing new lesion formation.

There is a high frequency of postpartum exacerbation, and physicians must be prepared to quickly reinstitute or increase therapy at the time of delivery.

Fewer than 5% of the infants of mothers with pemphigus gestationis will have vesiculobullous lesions, which are usually mild and transient. Infants exposed to high doses of corticosteroids should be monitored for adrenal insufficiency.

The immediate and vigorous treatment in our case probably inhibited the formation and deposition of the immune complexes in the placenta and therefore prevented placental insufficiency, although the maternal disease was fulminant.

A pregnancy complicated by pemphigus gestationis should be considered to be a high-risk pregnancy and should be monitored and managed accordingly.

Pelvic denervation for chronic pain associated with endometriosis: Fact or fancy?

Paolo Vercellini, MD, Luigi Fedele, MD, Stefano Bianchi, MD, and Giovanni Battista Candiani, MD

Milan, Italy

The efficacy of presacral neurectomy and amputation of the uterosacral ligaments in the treatment of chronic pelvic pain has been debated for decades. These procedures used to be done mainly in women with normal pelves, but more recently they have been performed during conservative surgery for treatment of endometriosis. In the 1980s the rapid spread of laparoscopic surgery has led to an increasing number of endoscopic denervations in patients with chronic pelvic pain associated with endometriosis. However, an analysis of literature data has failed to prove that presacral neurectomy and amputation of the uterosacral ligaments are effective and did not demonstrate better results with the use of lasers rather than electrocoagulation. Moreover, no valid comparison has yet been made between laparotomy and laparoscopic methods. (AM J OBSTET GYNECOL 1991;165:745-9.)

Key words: Pelvic pain, dysmenorrhea, dyspareunia, endometriosis, presacral neurectomy

Chronic pelvic pain is frequently associated with endometriosis.[1-3] Most studies on conservative treatment of this disease have considered the results mainly in terms of fertility, and the most effective management of pain symptoms in women wanting children is still a matter of debate.

In 1899 the Italian Ruggi[4] and the Frenchman Jaboulay[5] published the first descriptions of presacral nerve resection in women with severe dysmenorrhea. During the first half of this century presacral neurectomy was performed increasingly in both Europe[6] and the United States.[7-9] In the 1950s Doyle[10] demonstrated the efficacy of paracervical denervation for the relief of dysmenorrhea by abdominal or vaginal transection of uterosacral ligaments. Until then, pain in women with normal pelves had rarely been differentiated from pain associated with pathologic conditions such as chronic pelvic inflammatory disease or endometriosis. The advent of nonsteroidal antiinflammatory drugs allowed effective treatment of most women with "essential" dysmenorrhea. Consequently, during the 1960s and 1970s there was a fall in the number of pelvic denervations, which were performed mainly during conservative surgery for severe pelvic endometriosis. During the 1980s it gradually became clear that the possibilities of medical "cure" for endometriosis were limited[11, 12] and interest in pelvic denervation underwent a corresponding resurgence, enhanced by the progressive widespread use of operative endoscopy performed with high-tech methods.[13]

Different views have alternated with various generations of surgeons, but the basic problem is still unresolved: Does the performance of pelvic denervation in addition to the standard excision of ovarian and peritoneal lesions significantly increase the well-being of patients with endometriosis or only increase the risk of intraoperative and postoperative morbidity?

We have analyzed the recent literature data in an attempt to clarify the usefulness of presacral neurectomy and amputation of the uterosacral ligaments in women with chronic pelvic pain associated with endometriosis, comparing the pain relief obtained by classic and endoscopic surgery.

Pelvic denervation at laparotomy

Few clinical studies have been designed to evaluate the efficacy of conservative laparotomy for endometriosis specifically in terms of pain relief (Table I). Furthermore, the disease stage has not always been specified.

*Mixed pelvic disease.

Garcia and David[14] performed a retrospective analysis of postoperative pain symptoms in 71 patients who underwent conservative surgery for endometriosis and found that in the 35 women who underwent presacral neurectomy dysmenorrhea and dyspareunia decreased significantly with respect to the 36 controls (97% vs 72% and 74% vs 58%). In another retrospective study Puolakka et al.[15] compared 45 women undergoing simple resection of endometriotic lesions with 51 in whom presacral neurectomy also was performed. Pain symptoms resolved or were markedly attenuated in 80% of the former and 90% of the latter. Although the authors considered a 10% difference to be of importance, it does not seem statistically significant.

In Polan and DeCherney's study[16] the combination of presacral neurectomy with conservative surgery in women with chronic pelvic pain, endometriosis, or pelvic inflammatory disease increased the percentage of total postoperative pain relief from 26% to 75%, but the mixed pelvic disorders and the small number of patients studied make it difficult to draw conclusions. Lee et al.[17] performed presacral neurectomy in 50 women with chronic pelvic pain, and dysmenorrhea resolved in 73% of the cases, dyspareunia lessened in 77%, and acyclic pain showed improvement in 63%. The uterosacral ligaments were resected in half of the subjects in the study, but this did not improve the pain relief rates. Again no definitive conclusions can be based on this study because of the inclusion of mixed pelvic disorders.

Recently, Tjaden et al.[18] published the combined results of a randomized study and a comparative nonrandomized study performed in patients with moderate or severe endometriosis and chronic pelvic pain who underwent conservative surgery with or without presacral neurectomy. These authors divided dysmenorrhea into midline and lateral categories on the basis of the differences in sensory innervation and observed that midline pain was abolished in all four patients randomized to neurectomy versus none of the four controls who underwent only resection of pelvic endometriotic lesions. These data, together with similar findings in a group of 18 nonrandomized women, led the monitoring committee to stop the study because "it was considered unethical to continue to deprive patients with midline dysmenorrhea of the benefit of pain relief that could be afforded with presacral neurectomy." Somewhat surprisingly, there was no difference between cases and controls in relief of dyspareunia.

Because of numerous biases in the design of most of the studies, constructive comments cannot be made on laparotomy for treatment of pelvic pain in patients with endometriosis. Almost all the reports are retrospective and observational without a randomized control group, the extent of endometriosis is rarely indicated, sometime different pelvic diseases are accumulated (such as endometriosis and pelvic inflammatory disease), the sample sizes are limited, the follow-ups are variable, and an objective evaluation of the pain symptoms on the basis of a multidimensional verbal score and/or a visual analogue pain scale[24, 25] has almost never been performed prospectively. Recently, amputation of the uterosacral ligaments was considered in a report[17] in which the authors observed similar results in women who underwent neurectomy regardless of whether the uterosacral ligaments were or were not resected. Thus whether similar pain relief is achieved by resection of the uterosacral ligaments alone and by presacral neurectomy is still an open question. This could be interesting since in women with endometriosis the uterosacral ligaments may constitute a specific source of disabling pain.[26, 27] Furthermore, resection of the uterosacral ligaments at laparotomy is simple and safe, once the ureters are identified.[28, 29] Presacral neurectomy may result in morbidity, including severe bleeding,[17, 30] and constipation.[31] In the absence of verified advantages this operation could be limited to patients in whom identification of the uterosacral ligaments is difficult because of extensive endometriosis of the pouch of Douglas. Tjaden et al.[18] concluded that when the results of neurectomy are unsatisfactory, resection was incomplete or selection of the patients was inappropriate. On this last point Slocumb[32] has recently written that ". . . the success of presacral neurectomy reported in the literature is not consistent with the general clinical impression of ob/gyn practitioner and teaching faculty . . . in chronic pelvic pain patients, the localization of pain in terms of tender tissues rarely is limited to the uterosacrals and uterus alone. Many of these other areas not only are outside the areas of presacral innervation, but also are more amenable to other methods of pain treatment."

Pelvic denervation at laparoscopy

Almost all authors who have reported the results of laparoscopic neurotomy in women with endometriosis have not classified the extent of the disease or have given cumulative results for all stages (Table I). Furthermore, as Sutton[33] observed, most published series "suffer from the disadvantage that they are entirely retrospective and uncontrolled and sceptics can quite reasonably argue that there is a massive placebo effect with this kind of symptom, especially if it is treated with the sort of high-tech wizardry that is implicit in laser beam procedures."

Feste[19] reported the resolution or marked improvement of dysmenorrhea in 72% of 32 women with endometriosis and chronic pelvic pain after excision of the implants and resection of the uterosacral ligaments by carbon dioxide laser. In 22% of the cases the symptoms did not change and in 6% they worsened. Using a similar technique, after 15 months of follow-up Davis[20] observed a considerable improvement in dysmenorrhea in 135 of 146 women (92%) and in dyspareunia in 103 of 109 women (94%) with endometriosis without significant differences in relation to the revised American Fertility Society classification stages.[34] An improvement of dysmenorrhea was observed by Daniell[21] in 75% of 80 patients with endometriosis 6 months after laparoscopic resection of the uterosacral ligaments performed with the potassium-titanium-phosphorus laser fiber. Sutton and Hill[22] used a carbon dioxide laser to section uterosacral ligaments and reported pain resolution in 70% of 187 women with endometriosis, dysmenorrhea, and dyspareunia after a variable follow-up of 1 to 6 years. Lichten and Bombard[35] have performed the only randomized, prospective, double-blind study designed to evaluate the efficacy of laparoscopic uterine nerve ablation by means of bipolar cautery and scissors transection. Unfortunately the presence of endometriosis was one of the exclusion criteria, but the trial is interesting for the objective evaluation of the potential pain relief afforded by the method. A relatively homogeneous group of women were selected who had severe or incapacitating dysmenorrhea and no demonstrable pelvic abnormality at laparoscopy and who were unresponsive to nonsteroidal antiinflammatory drugs and oral contraceptives prescribed concurrently. Coexisting psychiatric illness was evaluated with the Minnesota Multiphasic Personality Inventory, and those with an abnormal psychologic profile were excluded from the study. The remaining 21 patients were randomized to the group undergoing laparoscopic uterine nerve ablation or to the control group at the time of the diagnostic laparoscopy. Neither the patient nor the clinical psychologist who conducted the interview at follow-up was aware of the group to which the patient had been randomized. None of the patients in the control group reported relief from dysmenorrhea whereas 9 of the 11 patients (81%) who had laparoscopic uterine nerve ablation reported almost complete relief at 3 months and 5 of them had continued relief from dysmenorrhea 1 year after surgery. Evaluation of pain symptoms only 3 months after treatment is not very reliable,[36] whereas at 1 year after the operation only 45% of the women continued to report relief from dysmenorrhea.

Endometriosis rarely provokes exclusively midline pelvic pain that can definitely be lessened by paracervical or presacral denervation.[37] According to Daniell,[21] "It is important to counsel the patients with endometriosis and chronic pelvic pain carefully preoperatively and make certain that they are aware that success is not guaranteed in all cases." The uncertainties surrounding laparoscopic uterine nerve ablation were eloquently commented on by Vancaillie and Schenken[38]: "As with presacral neurectomy, the value of endoscopic neurotomy in relieving pain symptoms has not been established. Further, the complications of this procedure are unknown, but potentially great, because of the proximity of the ureter, rectosigmoid, and uterine vessels."

Very few judgments may be expressed on laparoscopic presacral neurectomy because only one observational report has been published to date.[23] After operation, among 25 patients, one required laparotomy because of retroperitoneal bleeding, four continued to experience the original adnexal discomfort, and two underwent subsequent hysterectomy with bilateral salpingo-oophorectomy because of failure to respond to conservative management. Only further studies will clarify whether presacral neurectomy is less risky at laparoscopy than at laparotomy or if it should be enumerated among the many operations that may be done "differently."[39]

Comment

> The validity of all evaluative studies of any therapeutic procedures depends on the level of certainty that exists on what would have happened without it.
>
> *T. Tulandi and N. Cherry*[40]
> 1989

Conservative surgery for treatment of endometriosis should undergo a rigorous and comprehensive reexamination regarding pain resolution. Most women with endometriosis report both lateral and midline pain. It has not been definitively demonstrated that presacral neurectomy, resection of the uterosacral ligaments, or both, which affect only the midline component, offer significantly better advantages than simple resection of the lesions as far as the general well-being of the women is concerned. Severe complications may follow presacral neurectomy,[17, 30] and this procedure should probably be performed in highly selected cases rather than in all women undergoing conservative surgery for treatment of endometriosis. The proposed laparoscopic technique[23] does not seem to reduce the risks and is probably untimely with respect to the current uncertainties on the real indications for the operation. Similar considerations also are relevant to paracervical denervation. Daniell[21] has recently written, "There have been at least two deaths in North America resulting from bleeding from uterosacral ligaments that occurred when these were transected with CO_2 laser energy. To date neither of these case reports have been published." Accepting without question a fixed chain of events—chronic pelvic pain, endometriosis, and neurectomy (presacral or paracervical)—may create unfounded therapeutic expectations. The mere presence of pelvic endometriosis may not cause symptoms.[41] Endometriosis has been found in 15% of pain-free women undergoing laparoscopic tubal sterilization.[42] Even when the uterus is believed to be the cause of chronic pelvic pain, hysterectomy does not improve symptoms in one woman out of four.[43] A multidisciplinary approach to evaluate thoroughly the psychic, neurologic, intestinal, and orthopedic components of the reported symptoms has been suggested[44, 45] and may be proposed to patients before surgery is performed for relief of pelvic pain presumed to be of endometriotic origin. However, even in women with true endometriotic pain, the large area over which lesions are often distributed on the peritoneum and pelvic organs must not be forgotten.[37, 46] As advised by other authors,[18] a multicenter trial in which the eligibility criteria and surgical procedures are precisely described and carefully monitored would be opportune. So far, there are inadequate data to confirm or refute the effectiveness of presacral neurectomy and amputation of the uterosacral ligaments in the treatment of chronic pelvic pain associated with endometriosis.

A last comment concerns the instruments to be used in laparotomy and laparoscopic denervation. Soderstrom[17] maintains that, however delivered, "a watt is a watt," and that to date the clinical studies touting the benefits of laser over electrosurgery have not been convincing. Leaving aside the theoretic advantages that still have not been definitely proved, laser treatment, especially if endoscopic, is fashionable to the extent of figuring in the most widely circulated international magazines[48-50] that show laparoscopists armed with lasers proclaiming that "In 20 years, major abdominal surgery will be nearly extinct."[50] In the meantime the "traditional" surgeon can console himself with the words of Illingworth[51]: "That which is most up to date and new is not necessarily the best."

We are pleased to acknowledge the editorial assistance contributed by Alix Green and Luca Vercellini.

Inhibin subunits in human placenta: Localization and messenger ribonucleic acid levels during pregnancy

Felice Petraglia, MD,[a] Gian Carlo Garuti, MD,[a] Laura Calza', MD,[b] Veronica Roberts, PhD,[c] Luciana Giardino, MD,[b] Andrea R. Genazzani, MD,[a] Wylie Vale, PhD,[c] and Helene Meunier, PhD[d]

This study describes the difference in distribution and levels of inhibin α, βA- and βB-subunit messenger ribonucleic acids in human placenta during pregnancy. Northern blot analysis indicated that inhibin α messenger ribonucleic acid is present in placental extracts collected at the early stage of gestation. Hybridization to inhibin βA messenger ribonucleic acid was detected in the first trimester but in much lower levels. However, the intensity of the hybridization signal for inhibin α- and βA-subunit messenger ribonucleic acids was greater in extracts prepared from term placentas than in those from the first or second trimester of pregnancy. Low levels of inhibin βB-subunit messenger ribonucleic acid were observed only in extracts prepared from term placenta. At both early stage and term gestation trophoblast cells showed a positive fluorescent signal with the inhibin α-, βA- and βB-subunit–specific antisera. However, whereas inhibin α-subunit was localized in the cytotrophoblast, inhibin βB-subunit immunoreactivity was observed in the syncytial layer of the villi, and inhibin βA-subunit was widely distributed. The different distribution of immunoreactive inhibin subunits was confirmed by in situ hybridization, showing the different localizations of the inhibin messenger ribonucleic acids. These results showed that (1) human placenta produces the inhibin α- and βA-subunits as early as the first trimester of pregnancy, (2) messenger ribonucleic acid levels for each of the three inhibin subunits are highest at term, and (3) immunoreactive inhibin subunits are localized differently in placental villi. (AM J OBSTET GYNECOL 1991;165:750-8.)

Key words: Inhibin, activin, placenta, proteins, growth factors, pregnancy

Two new hormones, inhibin and activin, are produced by human placentas.[1-4] Indeed, placenta seems the major source of the high levels of circulating inhibin-like immunoreactivity in pregnant women.[5-7] Moreover, inhibin and activin modulate human chorionic gonadotropin (hCG) and progesterone release, suggesting a local paracrine or autocrine effect.[8,9]

Inhibin is a disulfide-linked heterodimer composed of an α-subunit and one of two distinct β-subunits (βA or βB), whose major biologic role is to decrease follicle-stimulating hormone release from pituitary gland.[10,11] The combination of two β-subunits (βA and βA, βA and βB, βB and βB) originates a dimer named activin, which increases pituitary follicle-stimulating hormone release.[10,11] However, there are not yet convincing methods to evaluate which forms of inhibins or activins are present in human placenta.

Earlier studies have described the presence of inhibin α-subunit immunoreactive material, in human term placenta[3] as well as inhibin α- and βA-subunit messenger ribonucleic acid (mRNA).[1,4] Rat placenta, on the other hand, produces mRNA encoding inhibin α-, βA- and βB-subunits.[12] However, no data on the possible different expression of the inhibin subunits in human placenta during pregnancy or on the localization of the inhibin β-subunits within placental villi are currently available. The goal of this study was to evaluate the expression of the respective inhibin subunit mRNAs and the cellular localization of these subunits in human placentas at various stages of gestation.

Material and methods

Tissue preparation. Placental tissue was collected from elective aspiration termination (8 to 10 weeks of

pregnancy, $n = 13$), from therapeutic abortion (18 weeks of pregnancy, $n = 2$), and from elective cesarean section (39 to 40 weeks of pregnancy, $n = 7$). For specimens collected at an early stage of gestation, the placental villi were distinguished from the decidual tissue according to the external appearances, with the use of a dissecting microscope. To confirm the absence of decidual or fetal tissues, a histologic evaluation of the specimens collected was carried out in parallel. The placental tissue from the second trimester and at term was collected within the central structure of the cotyledons, avoiding the basal plate. According to the following procedures, placental tissue was subdivided in three aliquots: (1) Some tissue was immediately placed in guanidine isothiocyanate and treated for ribonucleic acid (RNA) extraction and subsequent Northern blot analysis; (2) some trophoblast was immediately frozen in liquid nitrogen for immunohistochemistry; (3) part of the trophoblast was fixed in 4% paraformaldehyde for 8 hours before freezing for the in situ hybridization studies.

Northern blot analysis. The collected tissue samples were immediately homogenized in 4 mol/L guanidinium isothiocyanate, 25 mmol/L sodium citrate (pH 7), 0.5% sarcosyl, and 0.1 mol/L 2-mercaptoethanol, and total RNA was isolated.[13] Placental total RNA samples were pooled according to gestational age, and poly(A) mRNA enrichment was subsequently obtained by oligo(dT)-cellulose column chromatography. Total poly(a) mRNAs were quantified by ultraviolet absorptions at 260 nm, size fractionated by electrophoresis on 1.5% formaldehyde and agarose gel, and transferred to gene screen membranes (New England Nuclear, Boston). Three identical series of placental poly(a) mRNAs (5 μg; each sample from a different trimester of gestation) were electrophoresed and blotted on the filters. The experiments were replicated three times.

The complementary deoxyribonucleic acid (cDNA) containing human inhibin α, βA, and βB and γ-actin sequences were excised from the plasmid vector and purified by agarose gel electrophoresis. Deoxyribonucleic acid (DNA) labeled with DNA polymerase (Klenow Enzyme, Boehringer Mannheim, Mannheim, Federal Republic of Germany) in the presence of deoxyadenosine triphosphate and ^{32}P-a-deoxycytidine, with the random phosphate 32–α-priming technique (specific activity of 2 to 4 × 10^8 cpm/μg DNA was usually obtained).[13]

Blots were prehybridized in 4× SSPE (1× SSPE is 0.15 mol/L sodium chloride, 10 mmol/L sodium biphosphate, and 1 mmol/L ethylenediaminetetraacetate), 10× Denhardt's solution (1× Denhardt's solution is 0.02% Ficoll, 0.02% polyvinylpyrrolidone, and 0.02% bovine serum albumin), 0.1% sodium dodecyl sulfate, 0.2 mg/ml sonicated salmon sperm DNA, and 0.2 mg/ml yeast-extracted tRNA for 2 hours at 65° C. After addition of the labeled human inhibin α-, βA-, and βB-subunit probes (10^7 counts/min/ml), three independent hybridizations were carried out for 15 to 20 hours at 65° C. The filters were then washed in 0.2× SSPE and 0.5% sodium dodecyl sulfate at 65° C and exposed to Kodak X-AR film with an intensifying screen at −40° C for 48 hours. As an internal control, the filters also were hybridized with human γ-actin cDNA probe. Results shown are representative of three separate experiments. Autoradiograms were scanned with a laser densitometer (Ultrascan XL, LKB, Uppsala). The integrated values for the hybridization signal of inhibin α-, βA-, and βB-subunit mRNA were corrected according to the specific activity of each probe and were expressed as arbitrary densitometric units.

Immunohistochemistry. Serial sections (10 μm) were cut on a cryostat (Leitz, Rockleigh, N.J.) and mounted on glass slides coated with chrome alum and gelatin to prevent their detachment during the incubations. The slides were then immersed in 4% paraformaldehyde in phosphate-buffered saline solution, pH 7.6 (15 minutes), washed in 0.1 mol/L phosphate-buffered saline solution (10 minutes), and incubated in the presence of the antiserum (diluted in 0.3% Triton X100 phosphate-buffered saline solution) for 18 hours at 4° C in a humid atmosphere. These highly specific antisera were used: (1) anti-inhibin α (1-26)-Gly-Tyr (dilution 1:400), (2) anti-inhibin βA (81-113) sodium hydroxide (dilution 1:1000), and (3) anti-inhibin βB (81-112) sodium hydroxide (dilution 1:500). These were affinity-purified polyclonal antisera raised in rabbit against porcine moieties. Their characteristics have been described in detail previously.[13] No cross-reaction between βA and βB antisera was observed. After rinsing in phosphate-buffered saline solution (3 × 10 minutes), the sections were incubated in the presence of the second antiserum (fluorescein isothiocyanate-conjugated swine antirabbit immunoglobulin) (Dako, Copenhagen) in 0.3% Triton X100 phosphate-buffered saline solution (30 minutes at 37° C). Once rinsed in phosphate-buffered saline solution, the sections were dried out, mounted in glycerol–phosphate-buffered saline solution (3:1 vol/vol) and examined with a fluorescent photomicroscope (Nikon Microphot-FXA, Tokyo). Control sections were preadsorbed with the synthetic immunogens or in the absence of the first antiserum.[13]

In situ hybridization. Antisense ^{3}sulfur 35–labeled RNA probes specific for the human inhibin α-, βA, or βB-subunit were generated by transcription for the SP6 or T7 promoters of linearized pGEM4 subclones, each to a specific activity of 5 × 10^7 to 1 × 10^8 counts/min/μg. The human inhibin RNA probe complementary to the α-subunit comprised 546 nucleotides, 353 corresponding to the mature portion of the

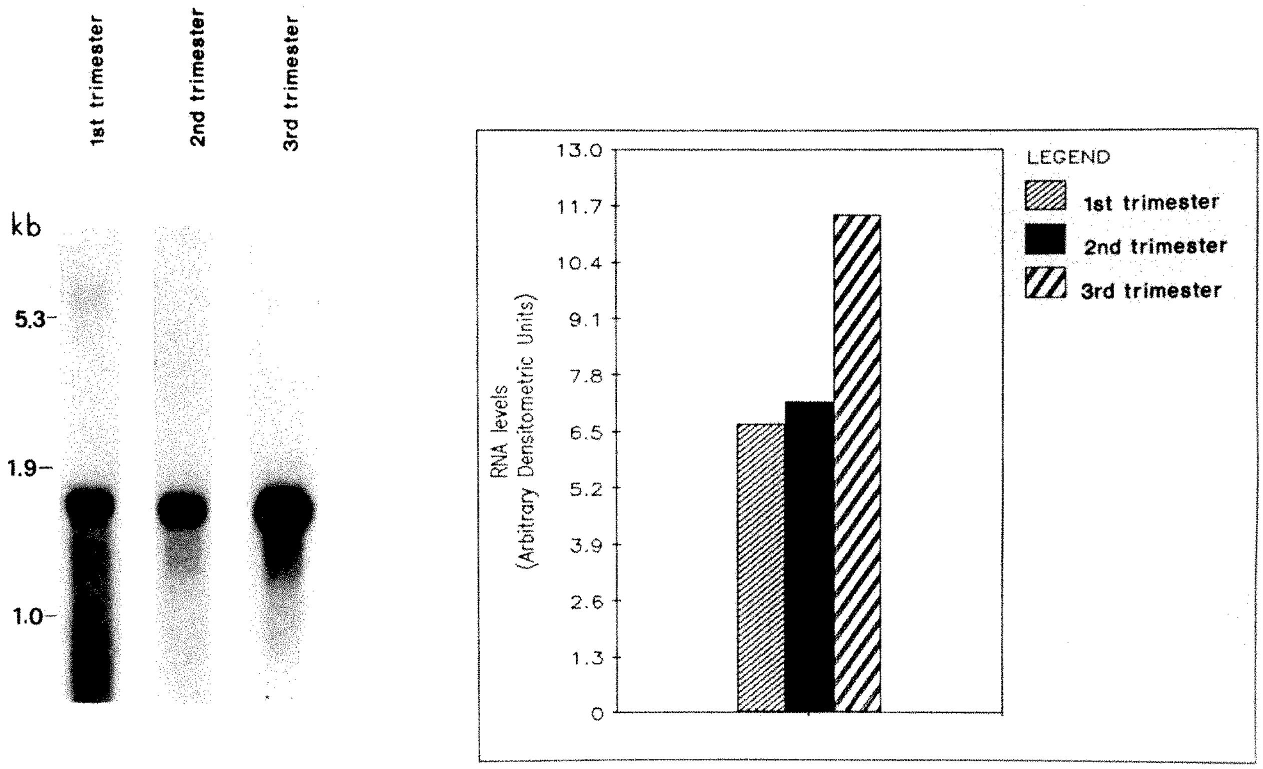

Fig. 1. Northern blot analysis of inhibin α-subunit mRNA in placental tissue at various gestational ages. Subunit mRNA is 1.5 kb. Quantitative evaluation of mRNA levels after hybridization revealed highest levels at term. For each lane 5 μg of poly(A) mRNA was electrophoresed.

molecule and 193 trailing into the 3′-untranslated region. The inhibin βA and βB mRNA probes were 338 and 320 nucleotides in length, respectively. The complementary RNA probe specific for the βA-subunit included 222 nucleotides spanning the mature region and 116 spanning the 3′-end untranslated region. The probe complementary to βB mRNA contained nucleotides from the 3′-end. Background levels were determined with a sense mRNA probe for the inhibin α-subunit (353 nucleotides). Differences in hybridization patterns suggest that the βB mRNA probe does not cross hybridize with βA-subunit mRNA.[11]

Inhibin-subunit mRNA was detected by the method previously described.[11] Frozen tissue was cut on a cryostat (20 μm) and mounted on poly-L-lysine–coated slides. Sections were incubated at room temperature for 30 minutes in the same fixative used for perfusion, rinsed, incubated at room temperature for 10 minutes in 0.5% Triton X100 in 0.1 mol/L Tris, 0.05 mol/L ethylenediametetraacetate, pH 8.0 buffer, and then rinsed. Dehydrated sections were incubated for 16 hours at 63° C with labeled RNA probes. After ribonuclease I (20 μg/ml) treatment, desalted sections were washed in 15 mmol/L sodium chloride/1.5 mmol/L sodium chloride with 1 mmol/L dithiothreitol at 55° C for 30 minutes. After successive alcohol dehydration, the sections were exposed to β-max hyperfilm (Amersham, Arlington Heights, Ill.) for 1 or up to 3 days. Slides were then defatted, dipped in nuclear tract emulsion (NTB-2, Kodak), and exposed for 18 days. After development (Kodak D19) and fixation (Kodak, Ektaflo), slides were stained with hematoxylin and eosin. Photographs were taken with Ilford XP1 film.

Results

Expression of inhibin subunit mRNA in placental tissue. A considerable difference in the degree of expression of the inhibin α-, βA-, and βB-subunits was observed among the tissue samples collected at the various trimesters of gestation. Placental tissue at first trimester of pregnancy expressed intense inhibin α and slight βA (Figs. 1 and 2) but not inhibin βB-subunit mRNA. The mRNA levels of the α- and βA-subunits in the placental tissue collected in the second trimester

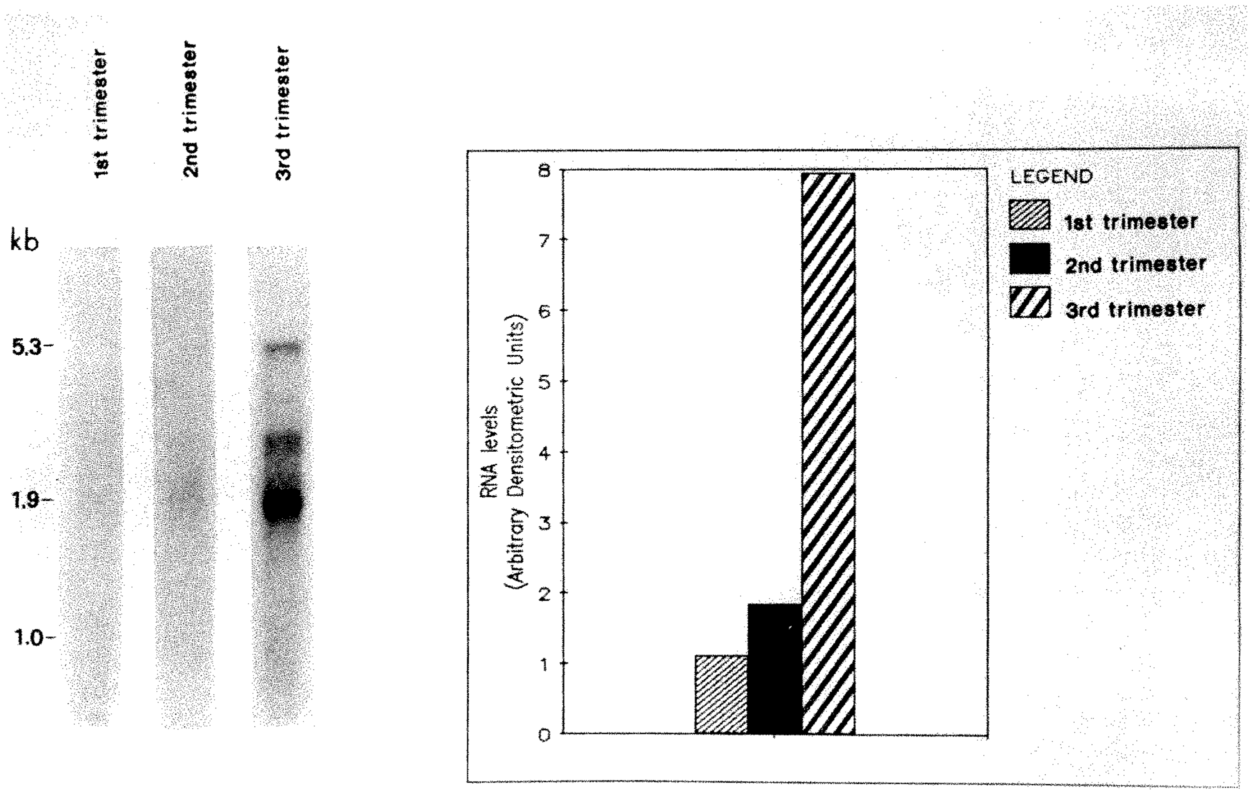

Fig. 2. Northern blot analysis of inhibin βA-subunit mRNA in placental tissue at various gestational ages. Three main species of βA mRNA were found: 5.3 kb, 2.9 kb, and 1.9 kb in size. In all placental samples 1.9 kb mRNA was most intense, suggesting that 5.3 and 2.9 kb mRNA species could present partial splicing products.[4, 11] Levels of mRNA were highest at term. For each lane 5 μg of poly(A) mRNA was electrophoresed.

were similar to those found in the first-trimester placentas. Placental tissue at term contained the highest levels of α- and βA-subunit mRNA (Figs. 1 and 2). Low levels of inhibin βB-subunit mRNA were observed only in placental tissue at term. The intensity of the hybridization signal for the βB-subunit was much lower and required a longer exposure time (data not shown). Supporting the specificity of the gestational changes of inhibin subunit expression, γ-actin mRNA levels did not vary with gestational age (Fig. 3).

Localization of inhibin subunits in placental tissue. Considerable variations were observed in the intensity and distribution of immunoreactive material (α, βA, and βB) between early and term gestation. In early pregnancy most immunoreactive inhibin α-, βA-, and βB-subunits were localized in trophoblast cells. However, positive immunostaining also was localized in the core of the villi (mesenchymal cells). An intense positive nuclear staining was observed in some preparations. In the first trimester inhibin α-subunit was found in cytotrophoblast columns or diffusely in the inner part of the villi (Fig. 4, *A* and *B*). The staining for inhibin βB-subunit was more intense and localized both in the inner (cytotrophoblast and villous core cells) and in the outer (syncytiotrophoblast) layers of the villi (Fig. 5, *A* and *B*). Immunoreactive inhibin βB-subunit was detected in the outer syncytial layer (Fig. 6, *A* and *B*). Preadsorption with the respective immunogens completely abolished the specific patterns of each antiserum (Figs. 4, 5, and 6, *C*). Similarly, the control sections incubated with the second antibody conjugate did not show any positive signal.

Staining was more intense in placental tissue collected at term than in tissue from early pregnancy for all three inhibin subunits. Again, the cellular distribution of the various inhibin subunits at term followed different patterns. Confirming our previous observation,[3] immunoreactive inhibin α-subunit was mostly localized in the cytotrophoblast cells and a light signal was observed in the syncytiotrophoblast (data not shown). An intense signal of immunoreactive inhibin βA was found in both cytotrophoblast and syncytial cells (Fig. 7, *A*), whereas

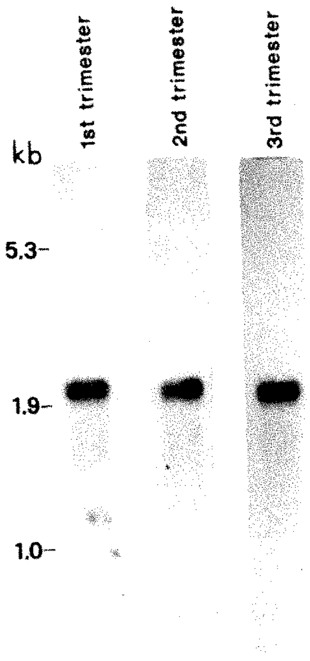

Fig. 3. Northern blot analysis of placental tissue at various gestational age with γ-actin cDNA probe. For each lane 5 μg of poly(A) mRNA was electrophoresed.

immunoreactive inhibin βB fluorescence was detected in the external layer of the villi (Fig. 7, *C*). Preabsorption with the respective immunogens competed efficiently for endogenous subunits, as recognized by the specific antisera (Fig. 7, *B* and *D*).

The in situ hybridization analysis revealed that inhibin subunit mRNA signals followed a different pattern of distribution as shown by immunoreactive proteins. The βA-subunit mRNA was the most distributed; signals were found both in the external layer and in the inner part of the villi (Fig. 8). The α-subunit mRNA was localized within the structure of the villi and a slight signal of βB-subunit mRNA in the syncytial cells (Fig. 8). Background levels of signals were partially detected in the various control slices, but grain density was lower than in experimental photomicrographs (Fig. 8).

Comment

These results show that human placentas produce inhibin α-, βA-, and βB-subunits with a gestation-related profile, the highest levels being observed at term. Moreover, while confirming that inhibin α-subunit is localized in cytotrophoblast and in some of the villous core cells, our data showed that in the placenta inhibin βA- and βB-subunits are subject to a different distribution pattern. Indeed, inhibin βA-subunit is distributed both in the inner and in the outer part of the placental villi, and the inhibin βB-subunit is almost exclusively localized in the syncytial cells.

Human placenta is one of the major examples of extragonadal expression of inhibin subunits. As previously suggested, the relative abundance of each inhibin mRNA may be indicative of which inhibin (αβ) or activin (ββ) dimer is produced in various tissues.[10, 15] The level of expression of the three mRNA inhibin subunits in placental tissue differed throughout pregnancy, leading us to suggest that the production of inhibin and activin changes during gestation. The gestation-related increase of inhibin α-subunit mRNA levels may reflect an increase in the synthesis of inhibin

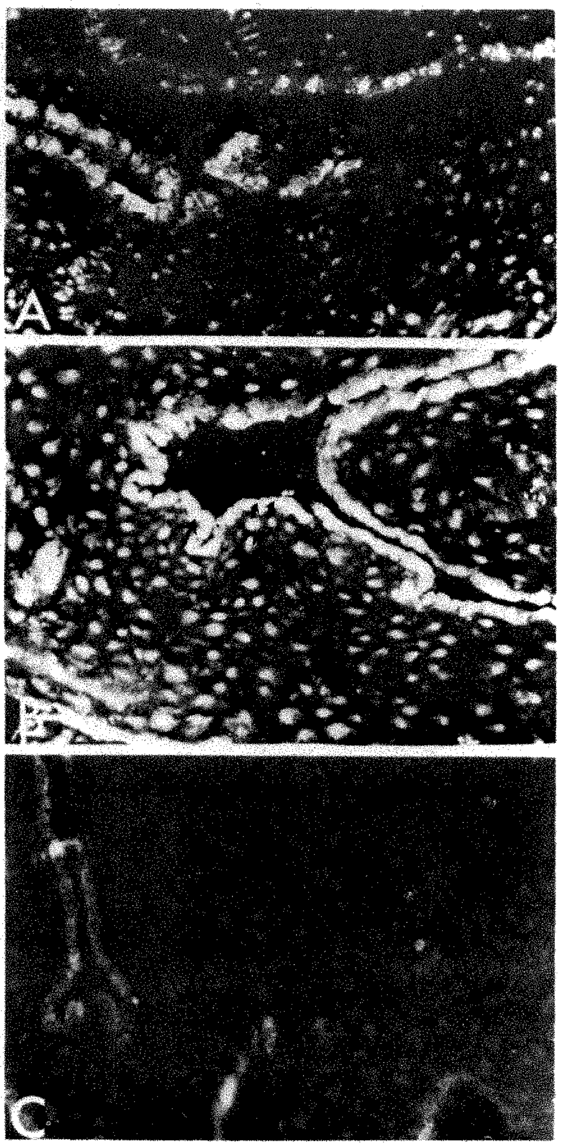

Fig. 5. Indirect immunofluorescence localization of inhibin βA-subunit in human placental tissue during first trimester of pregnancy (**A** and **B**). Fig. 6. Indirect immunofluorescence localization of inhibin βB-subunit in human placental tissue during first trimester of pregnancy. Syncytial cells are labeled by inhibin βB–specific antiserum. **C,** Control section after preadsorption with inhibin βB immunogen. (Original magnification × 160.)

during pregnancy. This hypothesis is supported by the increased levels of maternal plasma inhibin, as described in healthy pregnant women.[2] The synthesis of several placental hormones increases during gestation,[16] and a possible correlation between the inhibin subunit level changes and the other hormonal changes may be hypothesized.

The presence of both inhibin α- and βA-subunit mRNA in first-trimester placenta suggests that inhibin A (αβA) or activin A (βAβA) may be produced in the early stages of gestation. Small amounts of inhibin βB-subunit mRNA have been detected only in placentas collected at term, suggesting a late and low expression of the gene encoding the βB-subunit. However, immunoreactive inhibin βB-fluorescent material was observed in placental tissue collected in early pregnancy. The discrepancy between the undetectable or low βB-subunit mRNA signal and the presence of immunoreactive βB in the trophoblast tissue may be explained by the different sensitivity of the techniques involved. The Northern blot and the in situ hybridization analyses may not detect the very low levels of mRNA, whereas antisera are sensitive enough to detect small amounts of the corresponding protein. Another pos-

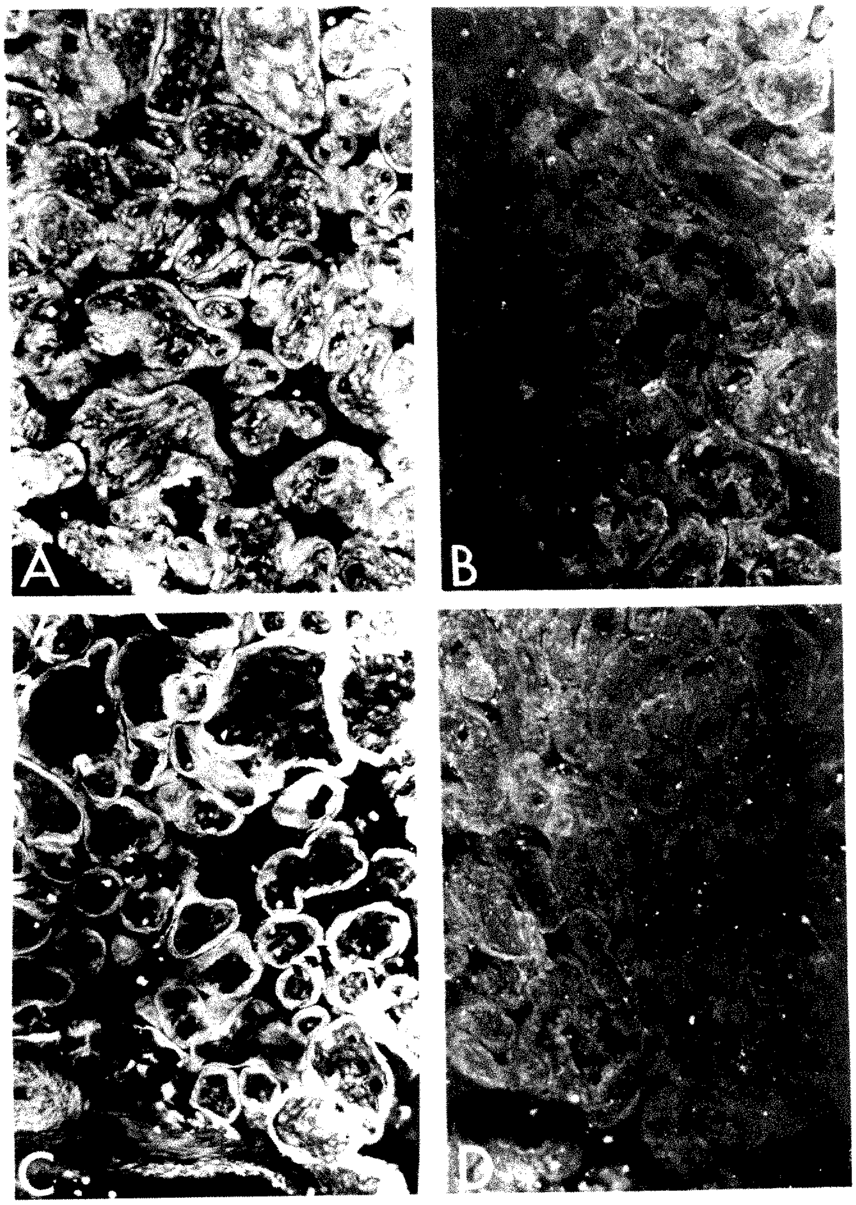

Fig. 7. Indirect immunofluorescence localization of inhibin subunits in human placental tissue at term. **A** shows widespread localization of immunoreactive inhibin βA-subunit material in inner and outer layers of placental villi. **C,** Syncytial cells positively staining inhibin βB-subunit. **B** and **D** show control section after preadsorption with βA and βB immunogens, respectively. (Original magnification ×210.)

sibility is that the βB-subunit mRNA in the syncytiotrophoblast cells may be subjected to rapid turnover. Alternatively, the immunoreactive inhibin βB-subunit present in the syncytial cells could be bound or sequestered from another source; only a limited amount results from a local synthesis. The same type of discrepancy between positive immunostaining and lack of detection of the βB mRNA signal has been described recently in rat testis.[14] The low signal in placental tissue is in contrast with the high levels of inhibin βB-subunit mRNA detected in human decidua throughout pregnancy.[13]

The different cellular localization of the respective mRNA inhibin subunits suggests that β-heterodimers and βB-homodimers, i.e., inhibin and activin, may have different sites of production. The presence of both α- and βA-subunits in the inner part of the villi could imply that inhibin A (α βA) and activin A (βAβA) may be produced by cytotrophoblast. The presence of βA- and βB-subunits in the outer part of the villi suggests that syncytial cells may synthesize the activins (βAβA, βAβB, βBβB).[10, 15] These results describing the distribution pattern of the inhibin subunits in human trophoblast resemble those previously described for an-

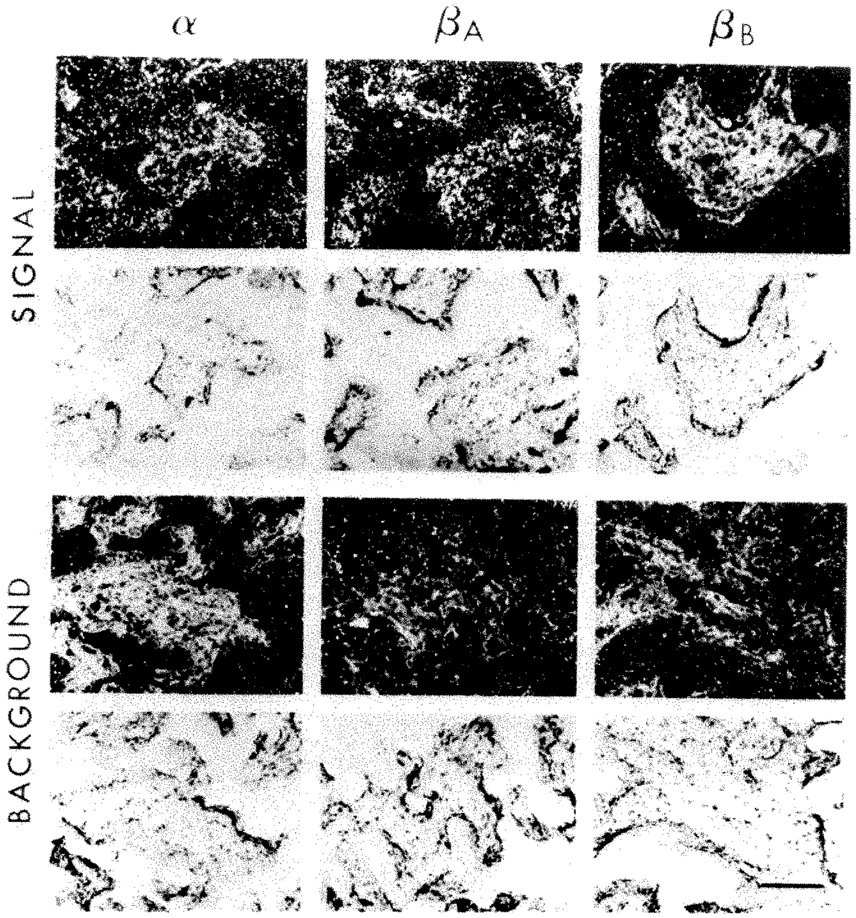

Fig. 8. Dark-field and bright-field photomicrographs show distribution of inhibin α, βA-, and βB-subunit mRNA, by in situ hybridization, in human placenta at term. α-Subunit mRNA is localized in centrally situated cytotrophoblast layer *(arrow)* of placenta villi, whereas βA-subunit mRNA is found in both inner and outer layers of villi. βB-Subunit mRNA signal is very low and is located in outer part of villi. Control mRNA photomicrographs show background levels of signals with labeled sense strand mRNA probe for each inhibin subunit. *Solid bar* represents 20 μm.

other typical placental glycoprotein of two subunits, hCG. In fact, whereas the hCG α-subunit mRNA is expressed in both cytotrophoblast and syncytial cells, the hCG β-subunit is expressed only in the syncytiotrophoblast.[16]

Therefore inhibin and activin may be included among the placental protein hormones, and multiple targets could be hypothesized. In defining a putative role of placental inhibin glycoproteins, both paracrine or autocrine and endocrine effects may be suggested. Indeed, gonadotropin-releasing hormone, progesterone, and gonadotropin-releasing hormone–induced hCG release from cultured placental cells is increased in the presence of activin and decreased after the exposure to inhibin.[8, 9] Moreover, the presence of placental inhibins in the maternal or fetal circulation[2, 3, 5, 7] suggests that maternal or fetal functions also may represent a target for those hormones or growth factors.[16]

In conclusion, our data revealed that human placenta all throughout pregnancy synthesizes the inhibin α-, βA-, and βB-subunits, indicating that the highest mRNA levels occur at term and that they have different cellular distributions. These results emphasize human placenta as one of the most important extragonadal sources of inhibin and activin.

We wish to thank Pamela Mellon, PhD (Salk Institute), for providing the γ-actin cDNA probe and Renata Battini for evaluating the mRNA scanning densitometry. Moreover, we acknowledge the help of Maria Cristina Galassi, Anna Mancini, Joan Vaughan, Sandra Guerra, and Beth Coyne.

Circadian rhythms of heart rate and mean arterial pressure in chronically instrumented pregnant rats

Paula J. Melone, DO, Paul J. Meis, MD, and David A. Blizard, PhD

Winston-Salem, North Carolina

With the use of a chronic preparation to directly monitor blood pressure and heart rate in pregnant rats, continuous data were obtained over the last half of gestation in normotensive rats. Over this time span, the animals showed significant decreases in blood pressure and increases in heart rate. Heart rate exhibited marked and consistent circadian rhythmicity with peaks occurring near the midportion of the dark phase of the 24-hour cycle. Blood pressure rhythms were less prominent and peaked later. The trends observed in blood pressure and heart rate over gestation suggest that the pregnant rat is a useful model for studying the cardiovascular effects of pregnancy. (AM J OBSTET GYNECOL 1991;165:758-63.)

Key words: Rat pregnancy, circadian rhythms, blood pressure, heart rate

In many mammals, including humans,[1-4] cardiovascular functions exhibit circadian rhythmicity. These rhythms, which have been described by many investigators,[1-6] are known to be influenced by the light-dark and rest-activity cycles. Because pregnancy imposes strong and progressive changes in maternal cardiovascular function in many species, including rodents,[7-10] we chose to examine the effects of pregnancy on circadian rhythms of heart rate and blood pressure in normotensive rats.

Although nonpregnant rats are known to demonstrate prominent circadian rhythmicity in many cardiovascular functions,[4-6] few studies exist to examine how these rhythms are influenced by gestation. Most previous investigations of cardiovascular rhythms in rats have used indirect (tail cuff blood pressure mea-

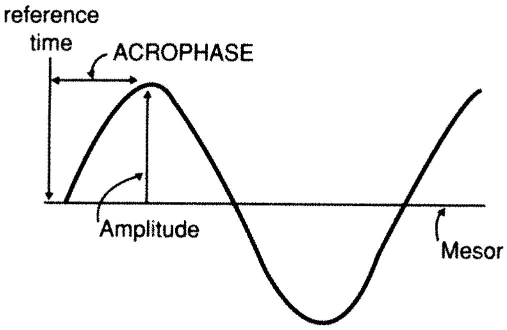

Fig. 1. Several measurable parameters of rhythmic behavior are shown: *Acrophase*, lag between reference time (12 midnight in 24-hour day) and time of rhythm's crest; *amplitude*, half of total predictable change in rhythm, *mesor* (Midline Estimating Statistic of Rhythm), average value of cosine curve fitted to data (usually halfway point between peaks and troughs of cosine curve).

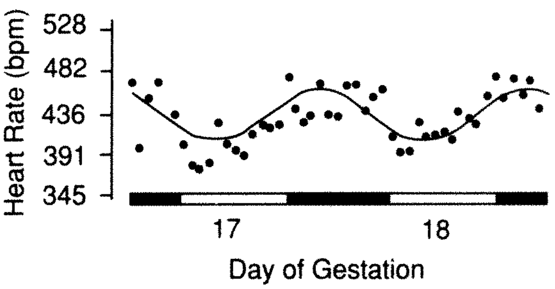

Fig. 2. 3M-63: Typical 48-hour plot of heart rate in one pregnant rat.

surements) methods to obtain data.[4-6] However, the restraint and warming involved in tail cuff measurements produce marked elevations in heart rate and (in some cases) blood pressure and are likely to obscure circadian rhythms.[11] Improvement measurement of cardiovascular functions can be achieved by chronic arterial cannulation. Reports published by several groups of investigators have described direct arterial blood pressure measurements in acute and chronic rat preparations.[10-13] Pan et al.[10] have described the use of this preparation in near-term pregnany rats. We are not aware of previous studies providing longitudinal data over a substantial portion of rat gestation. The object of this study was to develop a chronic model and to study circadian rhythms of cardiovascular functions longitudinally in pregnant rats throughout gestation. The hypothesis to be tested was whether circadian rhythms of blood pressure and heart rate were present.

Methods

Nine outbred Sprague-Dawley rats (Zelianople, Pa.) were used in the experiment. All facilities and procedures were approved by our Animal Care and Use Committee. One week of acclimatization to the 12-hours-light/12-hours-dark cycle was allowed before surgery. Surgery was performed on the eleventh day of gestation. The surgical procedure was an adaptation from the methods of Chiueh et al.[11] and Fejes-Toth et al.[14] The rats were anesthetized with ketamine hydrochloride (100 mg/ml) and xylazine (20 mg/ml), which were mixed in a 3:1 ratio and were administered intramuscularly (0.10 ml/100 gm body weight). The ventral surface of the tail and the nape of the neck were shaved and cleansed with 70% ethanol, a 2 cm incision was made in the base of the tail, and the middle caudal artery was dissected from its fascial canal. A 4-0 silk ligature was used to secure the distal artery. The vessel was incised, and a polyethylene catheter (PE-10 tip, PE-90 body) was inserted 8.5 cm through the artery to the abdominal aorta; the tip was placed just below the level of the renal arteries. The cannula was secured with 4-0 silk suture. The body of the cannula was tunneled subcutaneously via a trochar along the dorsal surface to exit centrally in the prepared area at the nape of the neck. The tail incision was closed withd 3-0 Vicryl (polyglycolic acid) suture. Steri-strips (3M Co., Minneapolis) were wrapped around the tail to prevent the animal from disturbing the surgical site and to provide wound support.

The neck incision was extended 1 cm parallel to the rat spine, and the skin was undermined. A 2 cm round piece of sterile Dacron netting was fixed with cyanoacrylate to the muscle. A Teflon button was secured with 1-0 Vicryl to the skin with transfixation via the subcutaneous Dacron netting, and a flexible stainless steel spring was attached to the button with Allen screws. Di-Trim (400 mg sulfadiazine and 80 mg/ml trimethoprim) was given intramuscularly (0.1 ml/100 mg) at the end of the surgical procedure. The rat was placed in a specially modified cage[15] and the cannula was secured to a fluid swivel (Instech Corp., Plymouth Meeting, Pa.), which permitted free movement of the animal without undue restraint. Cannula patency was maintained by a slow infusion (2 to 4 ml/24 hr) of heparinized saline solution (3.0 IU/ml) from a multichannel peristaltic pump (Ismatek SA, Zurich). Rats were fed Purina Rat Chow (Ralston Purina Co., St. Louis) and water as desired. The environmental temperature was maintained between 23° and 25° C. The light-dark cycle consisted of 12 hours of light and 12 hours of darkness; lights were turned on at 6 AM. The digitized, pulsatile output of a pressure transducer was sampled 2400 times per minute by an IBM-compatible computer. Systolic blood pressure, diastolic blood pressure, mean arterial pressure (MAP), and heart rate, which was computed from the arterial pressure wave, were averaged each minute and stored; 1-hour averages and their measures of variation were simulta-

neously printed out and stored on a floppy disk. Six-hour and 24-hour averages also were stored and printed. The program used was written by Dr. Dennis Wolf, Department of Physiology, Creighton University Medical School, Omaha.

Data analysis. Information from these chronically instrumented animals constituted a large and dense base of blood pressure and heart rate data collected over the last half of gestation. Over the course of the study, 2376 hourly intervals were examined, each of which was derived from 2400 samples for each minute of recording.

These data were examined by consecutive 48-hour epochs by individual animal and by group mean analysis of all animals for each 48-hour time span of gestation. The animals were allowed to recover from anesthesia and surgery. By day 13, when stable heart rates were seen, data analysis was begun. This analysis was continued through day 20 but was stopped approximately 36 hours before the onset of labor, because the process of parturition introduces other effects on blood pressure and heart rate. The presence of circadian rhythmicity in MAP and heart rate in the data was examined by single cosinor analysis.[16, 17] This technique uses the fitting of a cosine curve to the data by means of least-squares regression. A period of 24 hours was chosen as the cycle length to be examined. An F statistic was then used to test the zero-amplitude hypothesis for a circadian rhythm. For statistically validated rhythms ($p < 0.05$), the following parameters (and their 95% confidence intervals) were estimated: the mesor (rhythm-adjusted mean), the amplitude (half the total extent of the predictable change), and the acrophase (timing of the cosine wave peak). A depiction and definitions of these rhythmic parameters are shown in (Fig. 1).

In addition to this analysis of individual time epochs, the group mean cosinor technique was used to analyze grouped data from all pregnant animals at each successive 48-hour time epoch of gestation to evaluate the presence of population circadian rhythmicity.

The program for single and group mean cosinor analysis on a PC-compatible computer was provided by Dr. Bartholomew Hsi, University of Texas Health Science, Houston.

Results

Heart rate. A 48-hour plot of representative heart rate data is shown in Fig. 2. Single cosinor analysis demonstrated statistically significant circadian rhythms of heart rate in 34 of the 36 epochs examined. In those time series that exhibited rhythmicity, mean amplitude of the circadian rhythms was 24.72 beats/min (range 5.1 to 68.8). The acrophases or peak times of these rhythms ranged from 7 PM to 5 AM. Fig. 3 shows the plot of acrophase and amplitude of the epochs demonstrating circadian rhythmicity. This graph indicates a tight grouping of the peak times with most peak times occurring between 10 PM and 2 AM.

The group mean cosinor technique analyzed the presence of circadian rhythmicity from all animals that demonstrated statistically significant rhythms during a

particular 48-hour time epoch from days 14 and 15 to days 20 and 21. The results for heart rate are shown in Table I. Statistically significant circadian rhythms of heart rate are shown in each period of pregnancy for the pooled data. The timing of the peak heart rate (acrophase) ranged from 10:39 PM to 11:32 AM.

Blood pressure. A 48-hour plot of representative MAP data is shown in Fig. 4. Single cosinor analysis of mean arterial pressure demonstrated statistically significant rhythms in 24 of 36 epochs. In these 24 time series the mean amplitude of the rhythms was 2.92 (range, 0.51 to 8.0). During the first two sampling periods acrophases of MAP were variable and occurred at almost all hours of the 24-hour circadian time period. In the last two sampling times (days 18 to 19 and 20 to 21) the times of blood pressure rhythm peaks were much more consistent and clustered around 0. Fig. 5 plots MAP acrophase and amplitude and shows the wide range of dispersion of peak times and relatively low amplitudes of these MAP rhythms. Group mean cosinor analysis of MAP is shown in Table II. Statistically significant circadian rhythms could not be demonstrated in the two epochs 14 to 15 and 16 to 17 but were found for days 18 to 19 and 20 to 21. The mean or mesor of MAP decreased during gestation from 99.8 mm Hg at midgestation to 92.2 mm Hg at term (F ratio 10.50, $p < 0.01$); heart rate increased from 393 at midgestation to 417 at term (F ratio 15.22, $p < 0.01$). These trends in mesor are shown in Fig. 6.

The blood pressure and heart rate trends observed in the pregnant rats can be compared with data obtained from nonpregnant animals. Seven female Sprague-Dawley rats were instrumented and studied in a fashion similar to that used with the pregnant animals. After the rats had recovered from surgery, highly statistically significant circadian rhythms of heart rate were present, with acrophases tightly grouped from 10:40 PM to 1:46 AM. As in the pregnant rats, 24-hour blood pressure excursions were relatively small and were not as consistent as heart rate rhythms. In contrast to findings in the pregnant animals, no long-term trends in mesor (mean 24-hour) values of heart rate or blood pressure were seen in the nonpregnant rats.

Comment

This article represents, to our knowledge, the first description of directly measured blood pressure and heart rate followed longitudinally over the last half of the gestation in the rat. Arterial pressure signals were of high quality, and consistent recordings could be obtained from the eleventh day of gestation until term. The quality and quantity of the data obtained permitted precise analysis of circadian rhythmicity by means of single and group mean cosinor techniques. After the animals had recovered from surgery, the data were examined as 48-hour time epochs, because optimal rhythmic analysis uses epochs of at least double the period of the cycle examined.

Circadian rhythms of heart rate were present in individual animals in 94% of all the epochs studied. These rhythms were reliably present, were statistically significant, were of moderately large amplitude, and showed highly consistent timing of acrophases. In contrast, rhythms of MAP were demonstrable in only 67% of the epochs examined. When present, these rhythms were of low amplitude, and the timing of acrophase was more variable. Although group mean cosinor analysis of heart rate showed consistent and highly statistically significant rhythms, similar analysis of MAP was significant for only two time epochs. The lack of significance for earlier states of gestation was because the timing of the acrophase of rhythms in individual animals was variable and was likely to occur at any place on the 24-hour time span (Fig. 5). Thus peaks of MAP occurring at different times tended to cancel each other out when they were regarded as group data, and population-consistent rhythms could not be demonstrated. The appearance of significant group mean rhythmicity later in gestation occurred because MAP acrophases were synchronized within a closer range. This tighter synchronization of blood pressure rhythms may have been related to advancing gestation or to the possibility that MAP rhythms required a longer postsurgery recovery time when compared with heart rate rhythms to eliminate artifacts caused by surgery and anesthesia.

Previous research with the tail cuff technique has demonstrated a late gestational decline in blood pres-

sure in the rat,[8, 18] and studies that use short-term recordings from cannulated rats also have demonstrated that pregnant rats have lower MAP values than control rats 2 to 4 days before term.[9] Our continuous recordings from chronically cannulated rats supplement these previous observations by providing a detailed picture of the time course of the decrease in MAP during rat pregnancy. The decrease begins after the eighteenth day of gestation and continues until term (unpublished observations). During late gestation a pronounced and generalized vasodilation of maternal tissues coincides with final stages of placental maturation. The decrease in MAP can be understood to be a direct consequence of the reduction in total peripheral resistance that accompanies these vascular changes.[19]

The decrease in MAPs occurs in spite of the pronounced increase in cardiac output that has been primarily attributed, in the normotensive animal, to increased stroke volume that results from increased venous return.[11] However, these results clearly demonstrate an increase in heart rate, which is first seen on gestational days 17 to 18 and is maintained thereafter. These observations provide compelling evidence that chronotropic influences also support increased cardiac output in normotensive pregnant rats. Increases in heart rate in late-pregnant rats occasionally have been reported in studies of acute preparations.[15] However, the chronic preparation used, which results in minimal disturbance of the animals, provides important new information about the timing of heart rate increases and their relationship to the decrease in mean arterial pressure.

The reciprocal relationship between MAP and heart rate in late gestation raises the possibility that the baroreceptor reflex plays an important role in maintaining increased heart rate in the late-pregnant rat. This is an intriguing possibility because most previous research has emphasized the role of the baroreceptor reflex in controlling hemodynamic adjustments to phasic postural changes. In the late-pregnant rat increased heart rate is maintained over a 4-day time span (Fig. 6). If the baroreceptor reflex mediates the increased heart rate of late gestation, an explanation must be sought as to why the reflex does not adapt to the sustained decrease in blood pressure that occurs in late pregnancy. The discovery of the inverse relationship between heart rate and MAP in late pregnancy emphasizes the value of the chronic preparation in evaluating the relationship between longitudinal changes in specific hemodynamic systems.

Controversy exists regarding whether the pregnant rat is an appropriate or a useful model to better the understanding of the cardiovascular changes of human pregnancy. The characteristics of murine blood pressure and heart rate observed in this study show both similarities and differences when compared with data obtained from pregnant women. The increase in heart rate observed during murine pregnancy is similar to heart rate changes seen in human pregnancy.[20] Gestational blood pressure monitoring in human beings demonstrates a larger 24-hour amplitude than that seen in rats and has more clearly demonstrable circadian rhythmicity.[2, 3, 21] The recently published study by Cugini et al.[21] shows a decrease in mesor or mean 24-hour blood pressure in clinically healthy pregnant women that occurs in the second trimester and persists in the third trimester, although in the rats observed in this study the decrease in mesor of blood pressure was not seen until late in gestation. We suggest that, although the time of gestation when cardiovascular changes occur may differ between rat and human pregnancy, the direction of the trends is similar and the pregnant rat may be a useful model for studying the cardiovascular consequences of pregnancy.

In summary, we have demonstrated a model for the long-term evaluation of cardiovascular functions in pregnant rats. Highly consistent and statistically significant circadian rhythms were present in heart rate, as were somewhat less consistent rhythms in MAP. This model shows promise for studying regulatory mechanisms of blood pressure and heart rate in normotensive and hypertensive pregnant rodents.

Bilateral destruction of the fetal paraventricular nuclei prolongs gestation in sheep

Thomas J. McDonald, PhD, and Peter W. Nathanielsz, MD, PhD
Ithaca, New York

At present the origin of the signal(s) to initiate parturition remains unknown. Experimental studies in sheep have shown that interruption of the fetal hypothalamohypophyseal-adrenal axis will prolong gestation but no studies have shown prolongation of gestation after destruction of fetal neural structures. In this study we placed bilateral lesions of the paraventricular nucleus in five fetal sheep at 118 to 122 days' gestation. Cortiocotropin-releasing factor staining in the median eminence of the hypothalamus was markedly decreased after fetal paraventricular nucleus lesions. Paraventricular nucleus lesions prevented the fetal adrenocorticotropic hormone rise in response to hypotension and the normal predelivery increase in fetal plasma adrenocorticotropic hormone and cortisol and resulted in impaired fetal adrenal growth relative to the rest of the fetus. Lesioned fetuses had not been delivered at 157 days' gestation when they were removed by cesarian section to obtain tissue for histology. Four control fetuses were delivered at 146.5 ± 0.9 days' gestation (mean ± SEM). These findings indicate that a structure in the fetal brain, the fetal hypothalamic paraventricular nucleus, is necessary for parturition to occur. (AM J OBSTET GYNECOL 1991;165:764-70.)

Key words: Paraventricular nuclei, corticotropin-releasing hormone, parturition, adrenocorticotropin, fetal adrenal

The fetal sheep adrenals and pituitary play an indispensable role in the processes that initiate parturition. The classic work of Liggins et al.[1, 2] showed that bilateral adrenal or pituitary ablation delays parturition. Intravascular adrenocorticotropic hormone (ACTH) infusion to the fetus increases fetal adrenal cortisol production and plasma cortisol concentrations, followed by shortened gestation.[3, 4] Infusion of physiologic doses of cortisol into the fetus will also shorten gestation.[5] The preparturient rise in fetal plasma cortisol concentration starts at approximately 127 days' gestation[6] and is preceded by a small rise in fetal plasma ACTH concentration starting at 115 days' gestation.[7] However, to date no studies have clearly shown involvement of fetal neural structures in the fetal mechanisms that initiate parturition.

Corticotropin-releasing hormone, a 41-amino acid peptide that causes release of ACTH both in vivo and in vitro,[8] is present in highest concentration in the median eminence of the hypothalamus.[9] Most of the neurons in the median eminence that contain corticotropin-releasing hormone have their cell bodies located in the parvocellular portion of the paraventricular nucleus of the hypothalamus.[10, 11] Stereotaxically placed electrolytic lesions of the fetal paraventricular nucleus prevent the rise in fetal plasma ACTH concentration that normally accompanies fetal hypotension and hypoxemia.[12] In addition, small glucocorticoid implants placed adjacent to the paraventricular nucleus of fetal sheep not only block the normal ACTH response to hypotension and hypoxemia, but also eliminate immunostaining for corticotropin-releasing hormone in the fetal paraventricular nucleus and median eminence.[13] However, continuous peripheral intravascular infusion of corticotropin-releasing hormone to the sheep fetus does not always result in delivery or produce the normal decrease in maternal progesterone that precedes delivery.[14] In addition, pulsatile intravascular infusion of corticotropin-releasing hormone or arginine vasopressin (a second hormone implicated in ACTH release)[15] or a combination of corticotropin-releasing hormone and arginine vasopressin fail to result in any premature deliveries.[16] However, it is possible that these corticotropin-releasing hormone infusions to the fetus do not mimic normal corticotropin-releasing hormone release patterns.

We hypothesize that the fetal ovine paraventricular nucleus plays a critical role in the delivery of the signals that give rise to parturition. We therefore lesioned the paraventricular nucleus bilaterally in fetal sheep at 118 to 122 days' gestation to determine whether absence of information from these structures would prolong gestation. In both lesioned and sham-lesioned fetuses we measured fetal plasma ACTH and cortisol in the basal

state, after a hypotensive challenge to the fetus and at frequent intervals to assess any differences in preparturient changes in fetal plasma ACTH and cortisol between paraventricular nucleus lesioned–fetuses and controls.

Material and methods

Care of animals and surgical procedures. Nine Rambouillet-Columbia ewes were mated on a single occasion. To obtain fetal blood samples their fetuses were cannulated with polyvinyl catheters via the carotid artery and jugular vein inserted toward the fetal heart as previously described.[17] All ewes carried a single fetus. Surgery was performed at 118 to 122 days' gestation with coordinates derived from a modification of the stereotaxic atlas of Gluckman and Parsons (1983).[18] Two pairs of overlapping lesions were placed in the paraventricular nucleus of the fetal hypothalamus (lesion group, $n = 5$) (coordinates: AP 18 mm, V 12 mm, L 1 mm; AP 16 mm, V 11, L 1 mm where AP = anteroposterior, V = vertical, and L = lateral) with the use of a Radionics RFG-4A research RF lesion generator system (Kopf Tujunga, Calif.) The tissue temperature at the tip of the electrode was raised to 75° C for 30 seconds. In the sham-lesioned animals (sham group, $n = 4$) the electrode was lowered to the same coordinates without activation of the lesion generator.

All fetuses were allowed to recover for 5 days after surgery before being studied. At the end of the study the ewes and fetuses (lesion group) or newborn lambs (sham group) were anesthetized with halothane. To facilitate perfusion and fixation of the fetal brain the second fetal carotid artery was catheterized with a 14-gauge indwelling catheter pointed toward the brain. The jugular vein on the same side was cut. The fetal head was perfused with one liter of normal saline solution, containing 2.0% sodium nitrite (wt/vol) as a vasodilator, at room temperture, with the perfusion bottle at a height of 1 meter and infusion catheter wide open. Next, the anterior vena cava and anterior aorta were clamped. After this, 1 liter of 0.1 mol/L phosphate-buffered acrolein/paraformaldehyde (Sigma Chemical Co., St. Louis) (2.5/4% wt/vol) was perfused.

After perfusion the skull vault was opened and the brain and pituitary were removed. The hypothalamus was blocked out just anterior to the optic chiasm and caudal to the mammillary bodies, and the pituitary stalk was cut close to the pituitary. The tissue was sunk in several changes of 30% sucrose solution and then sliced at 30 μm on a Reichert freezing microtome. Sections were processed for corticotropin-releasing hormone with the avidin biotin complex method (Elite Kits, Vector Laboratories, Burlingame, Calif.) as previously reported.[19] Anti–corticotropin-releasing hormone was kindly donated by Dr. Wylie Vale of the Salk Institute and was used at a concentration of 1:50,000. The specificity of this antiserum for its respective antigen has been reported elsewhere.[9] Sections were counterstained with methyl green (0.2% wt/vol) and evaluated by light microscopy.

Hormone assays

ACTH. ACTH was measured directly in fetal plasma with kits purchased from INCStar (Stillwater, Minn.) with the following modifications. The assay used INCStar standard serially diluted to the appropriate concentration for the assay (4 through 80 pg · ml^{-1} in zero standard. Samples and control sera were thawed in an ice bath; ice-cold deionized water was used to prepare all INCStar reagents. Samples, antisera, and iodinated ACTH were aliquoted on ice into prechilled 12 × 75 mm borosilicate tubes. Standard, control sera, and sample (50 μl) were aliquoted per assay tube and incubated for 24 hours at 4° C with 50 μl of antisera. Radioiodinated ACTH (50 μl) was then added and further incubated for 24 hours at 4° C. Goat, antirabbit precipitating complex (150 μl) was added to all tubes (excluding total count tubes), and incubated for 20 minutes at room temperature after which 500 μl ice-cold phosphate-buffered saline solution 0.01 mol/L phosphate; 0.3 mol/L sodium chloride; 0.259/L thimerosal was added. The precipiated immune complex was pelleted by centrifugation at 3000 rpm for 30 minutes at 15° C and the supernatant immediately decanted.

Parallelism was shown by serially diluting control sheep and human plasma in zero standard (INCStar). Recoveries were made by the addition of a known quantity of standard to sheep and human control plasma. Interassay coefficients of variation for quality control samples of fetal plasma containing 28.7 ± 2.99 pg · ml^{-1} ACTH was 10.4% ($n = 10$). Intraassay coefficient of variation for qualtiy control sample containing 29.05 ± 1.76 pg · ml^{-1} ACTH ($n = 5$) was 6.1%. The limit of detection of this assay (i.e., 90% binding of radiolabeled ACTH in the assay tube) compared with the binding of radiolabeled ACTH in the absence of added ACTH (B/Bo) was 5.0 pg · ml^{-1}.

Cortisol[6] and progesterone[20] were measured by radioimmunoassay as previously described.

Blood samples

Daily samples. Fetal and maternal blood samples were taken once daily between noon and 3 PM. Blood sampling was started on day 5 after surgery and continued until term (sham group) or necropsy (lesion group). A total of 5 ml of fetal blood was taken from the fetal carotid artery at each sampling time. Blood samples were drawn into cold disposable plastic syringes, immediately chilled in ice, transferred to chilled heparinized 13 × 100 polypropylene tubes, and centrifuged at 4° C at 2000 rpm for 10 minutes. The supernatant

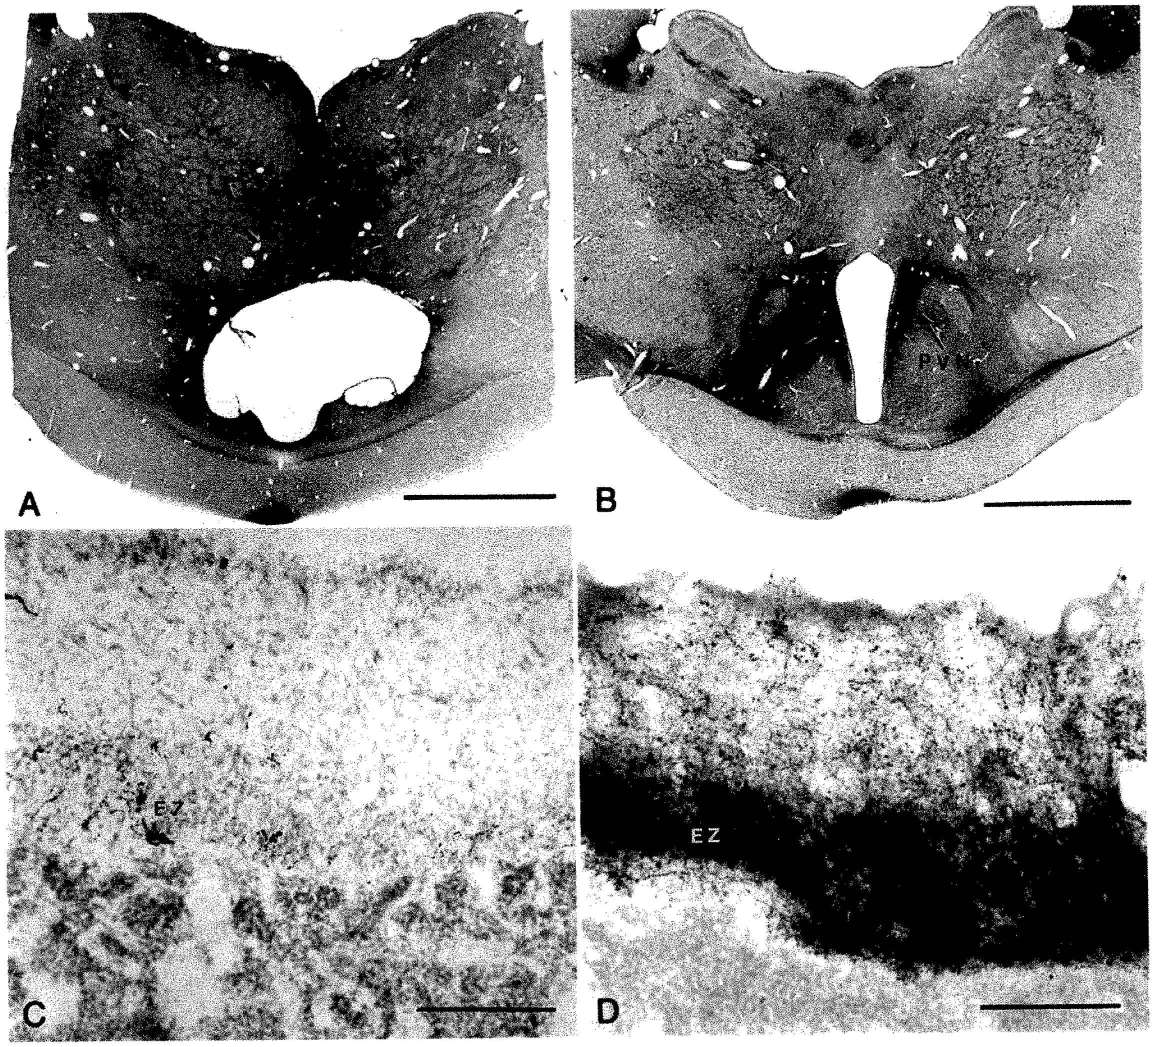

Fig. 1. Fetal hypothalamic sections stained for corticotropin-releasing hormone *(CRH)* **A,** Coronal section of brain in fetal sheep with bilateral lesions (lesion group) of the fetal hypothalamic paraventricular nucleus *(PVN)*. **B,** Coronal section of brain in fetal sheep with sham lesions (sham group) of PVN. **C,** Coronal section of median eminence *(ME)* of fetal sheep, lesion group, showing greatly reduced staining for corticotropin-releasing hormone in the median eminence external zone *(EZ)*. **D,** Coronal section of median eminence of sham group showing intense corticotropin-releasing hormone staining in the external zone. *Bars* indicate 3.75 mm (**A** and **B**) and 140 μm (**C** and **D**).

plasma was transferred to plastic vials, immediately flash frozen in liquid nitrogen, and stored at −20° C until assayed. After each sample, the fetal red blood cells were aseptically returned to the fetus.[21]

Fetal response to hypotension. Five days after surgery fetuses were subjected to a hypotensive challenge. Fetal mean arterial blood pressure was monitored with a Statham pressure transducer (P23ID) and recorded on a Grass polygraph (model 7). Heparinized fetal blood samples (5.0 ml per sample) were taken at −15, −5, +10, +20, and +30 minutes and monitored for blood gas, pH, and hematocrit values. Plasma was removed, frozen in liquid nitrogen, and stored at −20° C until assayed. Fetal blood pressure was reduced by 50% of baseline value by infusing nitroprusside in saline solution to the fetal jugular vein (starting at time = 0, at a rate of 100 $\mu g \cdot min^{-1}$ and adjusting the flow to effect). at +10 minutes the nitroprusside infusion was stopped and fetal blood pressure was allowed to recover.[12]

Blood gas values. Blood gas and pH values were measured on an ABLII blood gas analyzer (Radiometer, Copenhagen).

Statistical analysis

Fetal response to hypotension. The fetal plasma ACTH concentrations were averaged over both the prenitroprusside and postnitroprusside infusion periods to yield two independent data points for each animal. The average values for treated and control animals were then analyzed with the paired Student *t* test to assess increment within group and the nonpaired Student *t* test to compare the lesion group with the sham group.

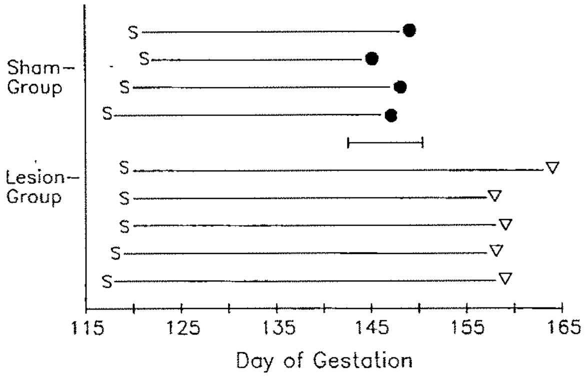

Fig. 2. Outcomes of individual preparations: Gestational ages at surgery *(S)* and spontaneous delivery (●) in sham lesioned group (sham group) or elected necropsy (∇) of fetal sheep with bilateral lesions of the hypothalamic paraventricular nucleus (lesion group). Age at spontaneous delivery of sham group was 146 ± 0.9 (x ± SEM); ├┤ represents 95% confidence limits for spontaneous delivery in sham group.

The Bonferroni correction was used for multiple comparisons.

Daily hormone concentrations. Average hormone concentrations for ACTH, cortisol, and progesterone on the last day of gestation in the sham-lesioned group are compared with the concentrations at term +10 days' gestation for the lesion group with the nonpaired Student *t* test with α set at 0.05.

Prolongation of gestation. Necropsy was performed at ≥157 days' gestation in the lesioned fetuses. We made the initial rationale that the controls in this study would behave similarly to our previous controls and be delivered at about 147.1 ± 5.27 days' gestation (mean ± SD; $n = 7$). We determined that if five animals went through the experimental protocol and had not been delivered by 157 days' gestation the probability for a one-sided test would be as follows:

$$\Pr(\bar{x} > 147) = \Pr\left(\frac{\bar{x} - \mu}{S/\sqrt{n}} > t\epsilon\alpha\right)$$
$$= \frac{147 - 157}{5.27\sqrt{5}} = -4.24$$

or $p < 0.01$. Because the days' gestation at necropsy were elected events and are therefore censored data, statistical comparisons are nonsensical.

Data throughout are presented as mean ± SEM except where noted otherwise.

Results

Fetal pH, P_{CO_2}, and P_{O_2} of the lesion group and sham group (7.38 ± 0.004 vs 7.37 ± 0.001, 50.9 ± 0.8 vs 51.1 ± 0.7 mm Hg, and 21.3 ± 0.4 vs 19.8 ± 0.8 mm Hg) averaged over the course of the experiment were not different.

Coronal sections through the brain and hypothalamus of the paraventricular nucleus—lesioned fetuses

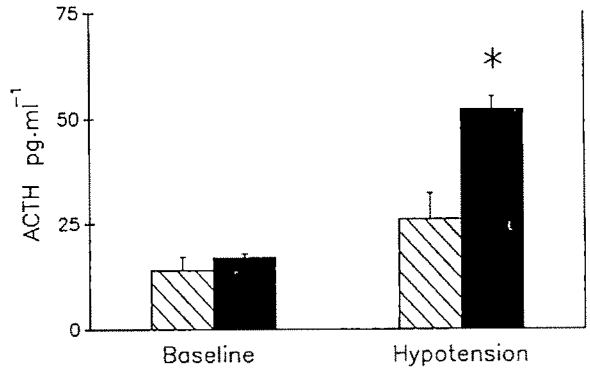

Fig. 3. Fetal plasma ACTH (mean ± SEM) in ovine fetuses with bilateral lesion of the hypothalamic paraventricular nucleus (▨) or sham lesion (■) in response to 50% drop in arterial blood pressure induced by nitroprusside infused intravascularly to fetus from 0 to 10 minutes at approximately 125 days' gestation. Baseline ACTH is average of two samples (−15 and −5 minutes). ACTH during hypotension is average of three samples (+10, +20, and +30 minutes after the commencement of hypotension). *$p < 0.05$ When lesion and sham groups are compared at same time period and compared with baseline in same group.

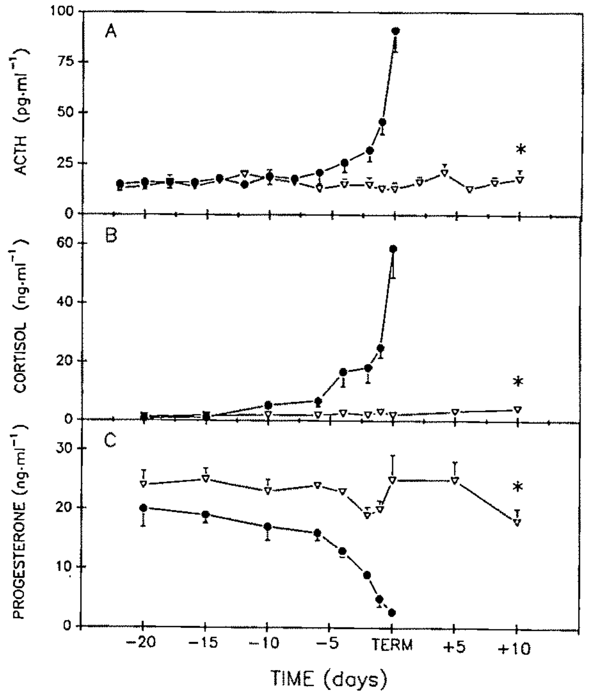

Fig. 4, A, Plasma ACTH concentrations of fetal sheep with bilateral lesions of the hypothalamic paraventricular nucleus (lesion group, ∇) or sham lesion (sham group, ●) from term −22 days' gestation to term +10 days' gestation (term, 146.5 ± 0.9 days' gestation, mean ± SEM in sham group). *$p < 0.05$ When compared with sham group at term. **B,** Plasma cortisol concentrations of lesion group (∇) or sham group (●) from term −20 days' gestation to term +10 days' gestation. *$p < 0.05$ When compared with sham group at term. **C,** Plasma progesterone concentrations of ewes bearing fetuses of lesion group or (∇) sham group (●) from term −20 days' gestation to term +10 days' gestation. *$p < 0.05$ When compared with ewes bearing sham group at term.

Table I. Body weight, combined adrenal weight, and organ weights of fetal sheep with bilateral lesions of the hypothalamic paraventricular nucleus or sham lesion

	Body weight (kg)	*Adrenal weight (mg)*	*Adrenals (% BW)*	*Heart (% BW)*	*Lungs (% BW)*	*Liver (% BW)*
Lesion group	5.26 ± 0.6*	487 ± 69.6	0.0096 ± 0.0014*	0.06 ± 0.07	3.2 ± 0.5*	2.1 ± 0.2
Sham group	3.5 ± 0.5	755 ± 123.6	0.0213 ± 0.0029	0.06 ± 0.03	1.8 ± 0.2	2.3 ± 0.3

BW, Body weight. Cesarean section of lesion group performed at ≥157 days' gestation; term of sham group = 146.5 ± 0.9 days' gestation.

*$p < 0.05$ When compared with sham group at term. Average absolute weight of adrenals of lesion group was not less than that of sham group but $p = 0.07$ when compared. Values are mean ± SEM.

(lesion group) and the sham-lesioned fetus (sham group) are presented in Figs. 1, *A* and 1, *B*, respectively. The lesions created were approximately 3 mm × 3 mm × 2 mm in diameter in the anteroposterior, vertical, and lateral directions, respectively. Lesions produced in all five fetuses were similar in size and location. When studied with light microscopy there was no consistent damage to other nuclei; the suprachiasmatic nucleus was damaged in one lesioned fetus but not in the other four. The anterior columns of the fornix were damaged bilaterally in all lesioned fetuses. Bilateral damage to the wall of the ventricle was inevitable in the lesion group. Generally, the lesion extended from the anterior aspect of the optic chiasm to the level of the median eminence. Immunocytochemistry revealed that there were a few scattered corticotropin-releasing hormone–positive cells left on the periphery of the lesion in two fetuses. However, the lesion-group had greatly reduced corticotropin-releasing hormone–staining in the external zone of the median eminence when compared with the sham-group fetuses (Fig. 1, *C*, and *D*).

The data on length of gestation are presented in Fig. 2. The fetuses of the lesion group were harvested at ≥157 days' gestation as shown. Average length of gestation for the sham group was 146.5 ± 0.9 days (mean ± SEM).

Fig. 3 shows the fetal plasma ACTH response to a 50% drop in mean arterial blood pressure produced by nitroprusside infusion at 5 days after surgery. Prehypotension baseline ACTH values were not different in the lesion group (14 ± 3.2 $pg \cdot ml^{-1}$) and sham group (17 ± 0.9). After hypotension the average fetal plasma ACTH concentration in the lesion group was 26 ± 6.1 $pg \cdot ml^{-1}$ and was not different from baseline. In contrast the sham group had average ACTH concentrations after nitroprusside hypotension that were greater than baseline (52 ± 3.2 vs 17 ± 0.9 $pg \cdot ml^{-1}$) ($p < 0.05$) and greater when compared with the lesion group after hypotension ($p < 0.05$).

Daily fetal plasma ACTH concentrations over the course of the experiment (Fig. 4) were all greater than the lower limit of sensitivity of the assay (5.0 $pg \cdot ml^{-1}$). The ACTH profile of the lesion group appears quite linear over the course of the experiment whereas that of the sham group shows the steep preparturient rise typical of intact fetuses. Ten days after term the lesion group still had less fetal plasma ACTH (18 ± 4.7 $pg \cdot ml^{-1}$) than the sham group at term (91 ± 10.4 $pg \cdot ml^{-1}$) ($p < 0.05$). The fetal plasma cortisol concentrations of the lesion group (Fig. 4, *B*) appear linear over the course of the experiment when compared with the sham group. Ten days after term the lesion group still had less ($p < 0.05$) fetal plasma cortisol (4.2 ± 1.8 $ng \cdot ml^{-1}$) than that of the sham group (58.8 ± 9.9 $ng \cdot ml^{-1}$). Even at 10 days after term the maternal plasma progesterone concentrations (Fig. 4, *C*) of the lesion group are typical of ewes before parturition and are greater ($p < 0.05$) than those of sham group at term (17 ± 1.2 vs 3 ± 0.8 $ng \cdot ml^{-1}$).

The data on body and organ weights are shown in Table I. The lesion group had larger body weights ($p < 0.05$) than those of the sham group (5.3 ± 0.6 vs 3.5 ± 0.5 kg). When expressed as percentage of body weight, adrenals of the lesion group were smaller ($p < 0.05$) than those of the sham group (0.0096% ± 0.0014% vs 0.0213% ± 0.0029%), lungs of the lesion group were larger ($p < 0.05$) than those of the sham group (3.2% ± 0.5% vs 1.8% ± 0.2%), and heart and liver were not different between the lesion group and sham group (0.6% ± 0.07% vs 0.6% ± 0.03%, and 2.1% ± 0.2% vs 2.3% ± 0.3%, respectively). In absolute terms, the adrenals of the lesion group were not different from those of the sham group (487 ± 69.6 vs 755 ± 123.6 mg, respectively) but the p value was 0.07.

Comment

The paraventricular nucleus was destroyed bilaterally in all lesion-group fetuses. The completeness of the bilateral paraventricular nucleus lesion was shown by the lack of corticotropin-releasing hormone–staining neurons in the normal location of the paraventricular nucleus (except a few scattered cells in two fetuses). In addition, the lesion group had greatly reduced corticotropin-releasing hormone in the external zone of the median eminence as determined by immunocytochemistry when compared with the sham group. At necropsy the lesion group had exceeded the average age of the sham group at term by 5 SDs and showed no signs of delivery.

Fetal plasma concentrations of both ACTH and cortisol of the lesion group at the time of necropsy were similar to those of the sham-lesion group early in the study and never showed the well-documented preparturient rise observed in normal fetuses in either ACTH[22] or corisol[6] and that occurred in the sham-lesion group (Fig. 4, *A*,and *B*). Likewise, by the time of necropsy maternal progesterone concentrations of the lesion group failed to exhibit the normal reduction that was seen in the sham group (Fig. 4, *C*) at term.

Fetal sheep with pituitary lesions[23] exhibit hypoplastic adrenals and prolongation of pregnancy without an increase in cortisol value above baseline. Antolovich et al.[24] were able to prolong gestation by disconnecting the pituitary from the hypothalamus (HPD) in fetal sheep while preserving the blood supply to the pituitary. Contrary to our findings in paraventricular nucleus–lesioned fetuses, HPD fetuses had baseline ACTH concentrations in plasma that were more than twice as great as the sham-HPD group at 133 to 138 days' gestation (127.5 ± 3.8 vs 60.2 ± 10.8 $\mathrm{pg \cdot ml^{-1}}$) and highest in postmaturity (145.2 ± 11.7 $\mathrm{pg \cdot ml^{-1}}$) without accompanying rises in cortisol. The discrepancy between the changes in fetal plasma ACTH and cortisol is hard to explain and suggests a difference in the responsiveness of the adrenals of the HPD fetuses to ACTH when compared with the sham-group fetuses.

It could be argued that the damage we observed to the fornix prevented the lesion group from delivery at term. However, it is well documented that lesions of the fornix in adult rats cause a hypersecretion of ACTH secretagogues into the portal system,[25] which, if anything, would have been expected to hasten delivery. It therefore seems logical to argue that prolongation of gestation was a result of loss of the paraventricular nucleus, a major contributor to the secretion of hormones into the portal system, rather than damage of the fornix. In any event our data show that destruction of the fetal neural structures in this area prolongs gestation.

The paraventricular nucleus is a large nucleus that has been shown to contain more than 30 neurotransmitters. If, as our results strongly suggest, the fetal paraventricular nucleus is a central participant in initiation of labor, what factor or factors contained therein are involved? Also, what pathways provide information on fetal maturity to the paraventricular nucleus or does it act as an anautonomous biological clock? In adults the corticotropin-releasing activity of the paraventricular nucleus via the median eminence is greatly influenced by inputs from the nucleus of the solitary tract, the amygdala and the hippocampus.[25-27] We hypothesize that a similar situation exists in fetal sheep, allowing the fetal brain to sum a multitude of sensory inputs in determining maturational status of the fetus to initiate parturition when a critical level of maturity has been achieved. Obviously further studies are needed to answer these interesting and challenging questions.

We thank Karen Moore for her help with the manuscript and Dean Myers for ACTH miniaturization.

The effect of interleukin-1 on adhesion formation in the rat

Avner Hershlag, MD,[a] Ivan G. Otterness, PhD,[b] Marcia L. Bliven, BS, MT(ASCP),[b] Michael P. Diamond, MD,[a] and Mary Lake Polan, MD, PhD[a]

New Haven and Groton, Connecticut

The potential role of interleukin-1 in postoperative adhesion formation was examined. Cecal abrasion gave a consistently higher adhesion score when compared with sham laparotomy, on the basis of adhesion number, density, and vascularity, and so was chosen for use in further studies. The extent of serosal bleeding during cecal abrasion did not affect adhesion scores. Intraperitoneal injection of 10 μg murine recombinant interleukin-1α in cecally abraded animals on the day of surgery and on the following 4 days resulted in a significant increase in adhesion scores when compared with those of cecally abraded animals injected with vehicle alone. Adhesions enhanced with murine recombinant interleukin-1α, which were thicker and more vascular, were equivalently enhanced at doses from 10 to 10,000 ng, implying maximal response over that range. Rats not operated on and receiving recombinant interleukin-1α 2 weeks after injury had increased adhesion formation. These results demonstrate that interleukin-1α may be an important short-term mediator of postsurgical adhesion formation. (AM J OBSTET GYNECOL 1991;165: 771-4.)

Key words: Adhesion, interleukin-1, cecum

Pelvic adhesions, which may result from a surgical procedure involving the parietal and visceral peritoneum or a primary inflammatory or infectious process, are of major concern to the reproductive surgeon because they can contribute to infertility. An understanding of the pathogenetic mechanisms of adhesion formation is important for studies aimed at developing strategies for their prevention.

One proposed mechanism for the formation of permanent fibrous adhesions is the inability of the injured peritoneum to remove deposited fibrin.[1] This may result from impaired production of plasminogen activators, which are responsible for the formation of plasmin and subsequent fibrinolysis. Such activity may be depressed with peritoneal injury.[1] DiZerega[2] has reviewed the pathologic features and pathogenesis of peritoneal healing. In the early period after injury (up to 3 days), the most pronounced elements in the healing lesion are polymorphonuclear cells and fibrin. Later there is an influx of new elements, including macrophages, mesothelial cells, and the development of angiogenesis. These infiltrating cells may release cytokines and other growth factors that may play a role in the adhesion process.

A few existing studies have led us to believe that cytokines such as interleukin-1 (IL-1) may be involved in both the normal healing response and the abnormal response to peritoneal injury that leads to postoperative adhesion formation. IL-1 is a cytokine produced by the host during the inflammatory response after microbial invasion or physical injury.[3] Multiple in vivo effects of IL-1 have been reported, including vascular endothelial inflammatory changes leading to expression of adhesion proteins, regulation of fibrin deposition and lysis, increase in collagenase production of fibroblasts, collagen type I and IV deposition by fibroblasts and epithelial cells, stimulation of fibroblast proliferation, and modulation of hematopoiesis and granulopoiesis.[3] The availability of recombinant murine IL-1[4] has allowed us to directly examine the potential role of IL-1 in peritoneal healing.

Material and methods

Rats. Female Sprague-Dawley rats (Charles River Breeding Laboratories, Wilmington, Mass.) weighing between 200 and 300 gm were maintained in accord with good husbandry standards and fed at will.

Surgical procedures. All procedures were performed with animals under general anesthesia with pentobarbital sodium (A.J. Buck and Son, Cockeysville, Md.), 39 mg/kg. Each animal was weighed, shaved, and earmarked. A midline abdominal incision was then made, first through the skin, then through the peritoneum. The cecum was identified and brought

through the incision. The distal 2 cm of the anterior cecum was scraped 15 times with a scalpel, rendering the serosal surface disrupted and hemorrhagic. The cecum was then dropped back into the abdomen, the peritoneum was closed by a continuous suture of 4-0 nylon, and the skin was closed with staples. In the sham laparotomy group, the skin and peritoneum were opened and then closed as described earlier. Surgery was tolerated well with no sequelae except for occasional incisional hernias. Weights were recorded in all experiments before procedures and before death, but no consistent pattern could be identified. Initially, rats were killed 2 weeks after surgery. Since we have found adhesions to be well formed within 1 week after surgery, subsequent scoring was done at a 7-day interval from surgery.

Adhesion scoring. Adhesions were scored by a blinded observer using criteria relating to extent and type, as shown in Table I. The total score in each animal represents a composite of individual scores given to each adhesion.

Recombinant IL-1α. Murine recombinant IL-1α complementary deoxyribonucleic acid was expressed in *Escherichia coli.*[4] The biologic activity of the recombinant IL-1α was verified in the lymphocyte-activating factor assay by binding to the IL-1 receptor on EL4 6.1 cells, by induction of colony-stimulating factor and cartilage resorption in vitro, and by induction of serum amyloid P, cerebrospinal fluid, IL-6, and fever in vivo. Endotoxin was less than one part in 100,000 by the Limulus assay. Phosphate-buffered saline solution was used as vehicle and placebo.

Statistics. Statistical analysis was performed by the Kruskal-Wallis nonparametric test or paired t test when appropriate.

Experiments

Cecal abrasion. Cecal abrasion was examined for suitability as a model of adhesion formation. Body weight was measured and recorded before surgery and again before death. Necropsy was performed 2 weeks after operation, and adhesions were recorded.

The effect of bleeding. Cecal abrasion can result in petechial hemorrhage at the serosal surface and occasionally in frank bleeding. To examine the effect of bleeding as a variable in the model that could alter the results in the cecal abrasion model, we selected a group of rats with more extensive bleeding from the vessels on the serosal surface of the cecum and compared them with the more typical cecal abrasion, i.e., a hemorrhagic surface but not bleeding.

Potentiation of adhesions by recombinant IL-1α. In this phase of the studies recombinant IL-1α was given intraperitoneally at a dose of 10 μg per rat diluted in phosphate-buffered saline solution to a total volume of 1 ml. This dose was chosen on the basis of previous work using continuous-infusion pumps of recombinant IL-1α.[5, 6] Injections were given daily for 5 days, starting on the day of surgery. Four groups of animals were studied: cecal abrasion with recombinant IL-1α, cecal abrasion with vehicle, no surgery and recombinant IL-1α, and no surgery and vehicle. In our initial experiments, necropsy was performed 2 weeks later and adhesions were scored. However, in later kinetic experiments we found that adhesion scoring did not change between 7 and 14 days after operation; therefore all subsequent necropsies were performed 7 days after cecal abrasion.

Dose response. Five daily intraperitoneal injections of recombinant IL-1α were given at four different doses (0.01, 0.1, 1, and 10 μg per rat, each in a total volume of 1 ml of phosphate-buffered saline solution) to cecally abraded animals. Vehicle was administered to a cecal abrasion control group. Animals were studied 1 week after laparotomy, and adhesions were scored.

Acute versus delayed effect of recombinant IL-1α. The effect of time of administration of recombinant IL-1α after surgery on adhesion formation was studied. Daily injections of 10 μg of recombinant IL-1α for 5 days were given to one group starting on the day of surgery and to a second group 2 weeks after surgery. Each recombinant IL-1α–treated group had a comparable vehicle-treated control group set up. Animals were killed 1 week after recombinant IL-1α injections were initiated, and adhesions were scored.

Results

Cecal abrasion. Adhesion scores were significantly and consistently higher in the cecal abrasion group than in the sham laparotomy group (mean ± SEM, 6.2 ± 0.6 vs 1.1 ± 0.1, respectively; $p < 0.05$). Adhesions resulting from cecal abrasion were typically between the cecum and the uterine horn, and often there was a second adhesion from the cecum to the small intestine or the other uterine horn. Because of the consistency of adhesion formation, this procedure was chosen for subsequent experiments.

Effects of bleeding. Adhesion scores did not differ in the two groups between animals with significant bleeding from the serosal surface and animals not

Table II. Effect of IL-1 on adhesion formation

Surgical procedure	*Treatment*	*No.*	*Adhesion score (mean ± SEM)*
Cecal abrasion	IL-1	6	14.3 ± 1.7*
Cecal abrasion	Vehicle	5	7.6 ± 0.9
No surgery	IL-1	5	0
No surgery	Vehicle	4	0

Treatment, Recombinant IL-1α was given at a dosage of 10 μg per rat intraperitoneally in 1 ml phosphate-buffered saline solution from the day of surgery for five daily treatments. Vehicle control received 1 ml phosphate-buffered saline solution. Scoring according to Table I 7 days after surgery.

*$p < 0.05$.

Table III. Effect of IL-1 dose on adhesion score after cecal abrasion

Dose of recombinant IL-1α (μg)	*No.*	*Adhesion score (mean ± SEM)*
0	6	3.0 ± 0.7
0.01	6	6.6 ± 1.1*
0.1	6	6.3 ± 1.3*
1	6	4.5 ± 0.8*
10	6	9.3 ± 1.4*

*$p < 0.05$ for vehicle-treated control. Scoring according to Table I 7 days after surgery.

Table IV. Adhesion development after cecal abrasion and short-term (days 0 through 4) versus delayed (days 14 through 19) administration of IL-1

Dosing schedule	*No.*	*Adhesion score (mean ± SEM)*
Days 0-4, recombinant IL-1α	6	14.0 ± 1.5*
Days 0-4, vehicle	6	6.5 ± 1.5
Days 14-19, recombinant IL-1α	6	3.2 ± 1.2
Days 14-19, vehicle	5	2.4 ± 0.7

*$p < 0.05$.

bleeding from the cecal abrasion (mean ± SEM, of 3.0 ± 1 vs 3.0 ± 0.7, respectively). This suggests that bleeding and fibrin do not increase adhesion formation. Therefore all animals, independent of the degree of hemorrhage, were used in all subsequent studies.

Potentiation of adhesions by recombinant IL-1α (Table II). With the nonparametric Kruskal-Wallis test, the four study groups were found to be different ($p = 0.00005$). Recombinant IL-1α given to cecally abraded animals resulted in significantly higher adhesion scores than those found in cecally abraded animals treated with vehicle. Adhesions associated with recombinant IL-1α injections were typically more extensive and more vascular. Adhesions were absent in animals undergoing only laparotomy, whether treated with recombinant IL-1α or vehicle alone.

Dose response (Table III). The Kruskal-Wallis test showed a difference between all groups ($p = 0.0244$), but when the control was removed and the same test repeated, groups given different recombinant IL-1α doses were then not different ($p = 0.09$). Adhesion scores were significantly higher in each group when compared with vehicle. Essentially the same potentiation of adhesion formation was obtained from 0.01 to 10 μg of recombinant IL-1α.

Short-term versus delayed effect of recombinant IL-1α (Table IV). The Kruskal-Wallis test showed a difference between the groups ($p = 0.0019$). Adhesion scores were significantly higher when cecally-abraded animals were given intraperitoneal recombinant IL-1α injections for 5 days beginning the day of surgery and for the next 4 days, then given vehicle alone, as previously shown. No adhesions were found when recombinant IL-1α was given for 5 days beginning 2 weeks after laparotomy and cecal abrasion.

Comment

Few studies have addressed the role of IL-1 in the normal and abnormal peritoneal healing response. Human recombinant IL-1 was found to enhance radiation-induced adhesions and death in mice.[7] In that study the timing of administration of IL-1 in relationship to the injury causing adhesions, i.e., radiation, was found to be critical. IL-1 enhanced adhesions when it was given daily from 3 days before radiation, including 1 day after; IL-1 did not enhance adhesions when given over the 4-day period after abdominal radiation. As the mechanism of radiation-induced injury may differ substantially from that of surgical injury, we thought it appropriate to study the effect of IL-1 directly after surgical trauma. In previous studies from this laboratory[5, 6] we examined the effects of IL-1 administered by continuous infusion with implanted osmotic pumps and observed that the pumps containing IL-1, but not those containing saline solution, became engulfed in granulation tissue that later contracted to a tough fibrous capsule. These results suggested to us that IL-1 might contribute to adhesion formation, and we therefore undertook this study.

IL-1 is synthesized and released in response to injury.[3] Thus, if it were to play a physiologic role in the healing process, it must be secreted in the period during and immediately after surgery. In addition, sepsis during surgery, particularly with gram-negative organisms, would be expected to augment IL-1 production.[8] We therefore elected to treat animals with IL-1 beginning with the completion of surgery. The intraperitoneal route was chosen to mimic the local production of IL-1. Daily intraperitoneal injection of IL-1 for 5 days, starting on the day of peritoneal injury, consistently resulted in increased adhesion scores 7 days after injury. In our pilot studies we observed that IL-1 causes (1) more adhesions and (2) more vascular adhesions; therefore a scoring system was developed so that each of these could be reflected separately in quantifying the IL-1 effect. No direct dose-response relationship was shown, since adhesion scores were similar from the lowest test dose of IL-1 (0.01 μg) to the highest test dose (10 μg) given, suggesting a maximal response over the tested dose range. Delayed administration of IL-1 2 weeks after injury did not increase adhesion scores above control level, thus suggesting that IL-1 enhanced adhesion formation only in the acute stage of peritoneal injury. When IL-1 was administered for 5 days to nontraumatized animals, it did not result in adhesions.

IL-1 could contribute at several different points to peritoneal adhesion formation. We have previously shown that IL-1 may lead directly to granuloma formation when given by continuous release by minipump[5] or as a slow-release encapsulated polymer.[9] However, with injection once daily it appears only to potentiate rather than to induce adhesion formation, suggesting that it acts to amplify the events occurring normally with surgical injury. IL-1 induces through a cyclic adenosine 5′-monophosphate–dependent mechanism the synthesis of both plasminogen activators[10] and inhibitors of plasminogen activity.[11, 12] In addition, IL-1 has been shown to induce the expression of adhesion proteins in endothelial cells.[13, 14] Moreover, IL-1 is a potent inducer of IL-8, an important chemotactic factor.[15] Since the extent of bleeding did not alter the adhesion scores, abnormal fibrinolysis may not be the entire pathogenetic mechanism responsible for adhesion formation in this model. We suggest as an alternative hypothesis that adhesion molecules that are not normally expressed in abdominal and pelvic structures are up regulated by IL-1. These adhesion molecules provide the substratum on which cell-cell adherence is enhanced and from which adhesions will ultimately form.[16]

As we have shown IL-1 to enhance the formation of adhesions, the question of whether endogenous IL-1 participates in the adhesion formation process becomes important. Since IL-1 is secreted by macrophages and other cells known to participate in the peritoneal response to injury, it seems reasonable to assume that IL-1 may be present and active in such circumstances. The amount of IL-1 liberated may be related to the extent of the inflammatory process either present in the peritoneal cavity at the time of surgery or directly induced by the trauma associated with surgery. Pelvic infection would be expected to further augment IL-1 production. Thus down regulation of interleukin may have therapeutic implications in the prevention of adhesion formation after gynecologic surgery.

Acute fetal ductal occlusion in lambs

Gerald Tulzer, MD, Saemundur Gudmundsson, MD, PhD, Kathleen M. Rotondo, MD, Dennis C. Wood, RDMS, RCPT, Grace Y. Yoon, MPH, and James C. Huhta, MD
Philadelphia, Pennsylvania

To assess fetal right ventricular and hemodynamic responses to acute occlusion of the ductus arteriosus, the pulmonary pressure, right and left ventricular output, and right ventricular dimensions of five fetal lambs were measured with simultaneous echocardiographic monitoring. Ductal occlusion resulted in a rise in pulmonary arterial pressure, a decrease in right ventricular output of 68%, an increase in left ventricular output of 18%, and a fall in combined cardiac output of 34%. The right ventricular systolic dimension increased, and the shortening fraction decreased from 0.41 to 0.14. Tricuspid regurgitation started within two heartbeats after ductal occlusion and resolved as soon as the occlusion was released. Acute fetal ductal occlusion imposes a marked increase in the right ventricular afterload, resulting in reversible triscuspid regurgitation. (Am J Obstet Gynecol 1991;165:775-8.)

Key words: Fetal ductus arteriosus, fetal echocardiography, cardiovascular hemodynamics

Fetal ductal constriction and triscupid valve regurgitation may occur in patients who have been treated with indomethacin for premature labor.[1, 2] It has been shown in animal experiments that chronic fetal ductal constriction-occlusion can cause morphologic pulmonary vascular changes from fetal pulmonary hypertension, resulting in persistent pulmonary hypertension of the newborn.[3-5] Degenerative myocardial changes in the right ventricular free wall and in the papillary muscles of the tricuspid valve after chronic ductal constriction were studied to determine the cause of tricuspid regurgitation.[6] There is, however, little known about the hemodynamic effects of acute fetal ductal constriction-occlusion of the right ventricle. To study acute changes in fetal right ventricular afterload, an animal model of acute fetal ductal occlusion was developed.

Material and methods

All animal experiments conformed to the guiding principles of the American Physiological Society. Five pregnant ewes (120 to 130 days' gestation; term is 148 days) were anesthetized with pentobarbital. The uterus was exposed by cesarean section; after the fetal chest and left forelimb were exposed through a uterine incision, fetal thoracotomy was performed in the third intercostal space. An electronic pressure catheter (Millar Instruments, Inc., Houston) was placed in the main pulmonary artery, and ultrasonographic flowmeters were placed around the main pulmonary artery and ascending aorta. Ultrasonographic measurements

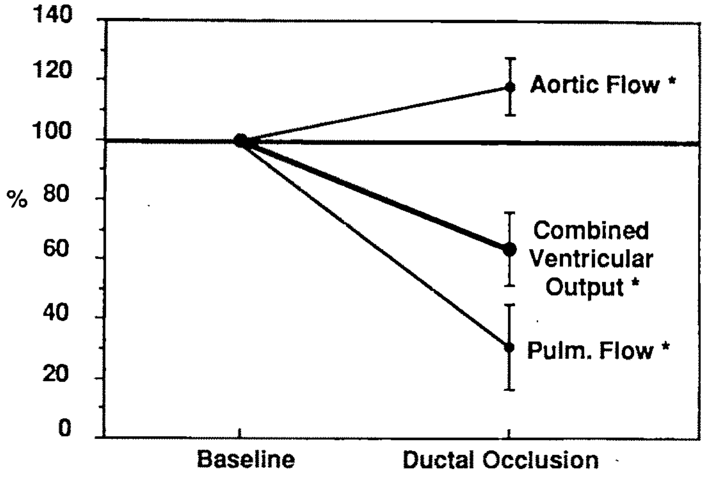

Fig. 1. Pulmonary flow, aortic flow, and total cardiac output changes during mechanical occlusion of fetal ductus arteriosus. Values are given as percentage change from baseline (mean ± SD).

(right ventricular end-diastolic and end-systolic dimension, tricuspid regurgitation) were performed (CFM 700, VingMed, Horten, Norway) with a 5 MHz sector scanner and 4 MHz continuous-wave Doppler echocardiography. We used color Doppler equipment to detect tricuspid valve regurgitation; continuous-wave Doppler echocardiography confirmed the holosystolic and high-velocity nature of the jets. The methods of DeVore et al.[7] were used to measure right ventricular shortening from the four-chamber view with M-mode echocardiography. The pulmonary artery pressure tracing was displayed on the ultrasonographic screen. Acute fetal ductal occlusion was mechanically induced for 30 seconds with a tightened rubber band placed around the ductus arteriosus. During multiple episodes of ductal ligature tightening, occlusion of the ductal flow was confirmed with continuous-wave Doppler echocardiography taken from the right ventricular outflow tract, as previously described.[8]

Each fetus served as its own control. Parameters recorded at baseline and during ductal occlusion were compared by using the paired Student *t* test. A p value of <0.05 was considered to be significant.

Results

During acute ductal occlusion there was a significant increase in pulmonary artery systolic and diastolic pressures from baseline level and a significant decrease in the ratio of pulmonary artery flow to aortic flow (Table I). Right ventricular end-diastolic and end-systolic dimensions increased gradually between 2 and 20 seconds after ductal occlusion with a substantial simultaneous decrease in right ventricular shortening fraction. The right ventricular diameter was unchanged at the onset of tricuspid regurgitation. Pulmonary flow decreased 68% (range 57% to 72%) from baseline, and aortic flow increased 18% (range 15% to 24%). Combined ventricular output fell 34% (range 24% to 55%; Fig. 1). Tricuspid regurgitation developed consistently within two heartbeats after the onset of ductal occlusion in all cases and disappeared immediately after the occlusion was released (Fig. 2). All physiologic parameters returned to baseline levels after the ductus arteriosus was reopened.

Comment

This animal model demonstrated that tricuspid regurgitation occurred immediately after an increase in right ventricular afterload. Main pulmonary artery flow decreased as pulmonary artery pressure rose. This was consistent with an inverse relationship between the afterload and stroke volume of a ventricle. There was also a significant increase in left ventricular output, probably because of right-to-left shunting across the foramen ovale and increased pulmonary arteriolar flow. This flow redistribution maintains peripheral organ perfusion and may explain the clinical experience that even severe ductal constriction is usually well tolerated for 2 or 3 days in the human fetus. However, because the increase in left ventricular output was less than the decrease in right ventricular output, the combined ventricular output fell, presumably in shocklike response to the acute stress of ductal occlusion.

The cause of the regurgitation of the tricuspid valve in this setting remains unclear. Perhaps the sudden demand to generate higher pressures resulted in changes of the right ventricular myocardial architecture affecting the papillary muscles of the tricuspid valve. That tricuspid regurgitation immediately disappeared with afterload reduction supports this hypothesis. Ischemia as the cause of triscuspid regurgitation is very unlikely because the intervals were not long enough for ischemic changes to develop and because the tricuspid regurgitation was immediately reversible. Thus tricuspid regurgitation in the early phase of ductal constriction need not be irreversible. To what

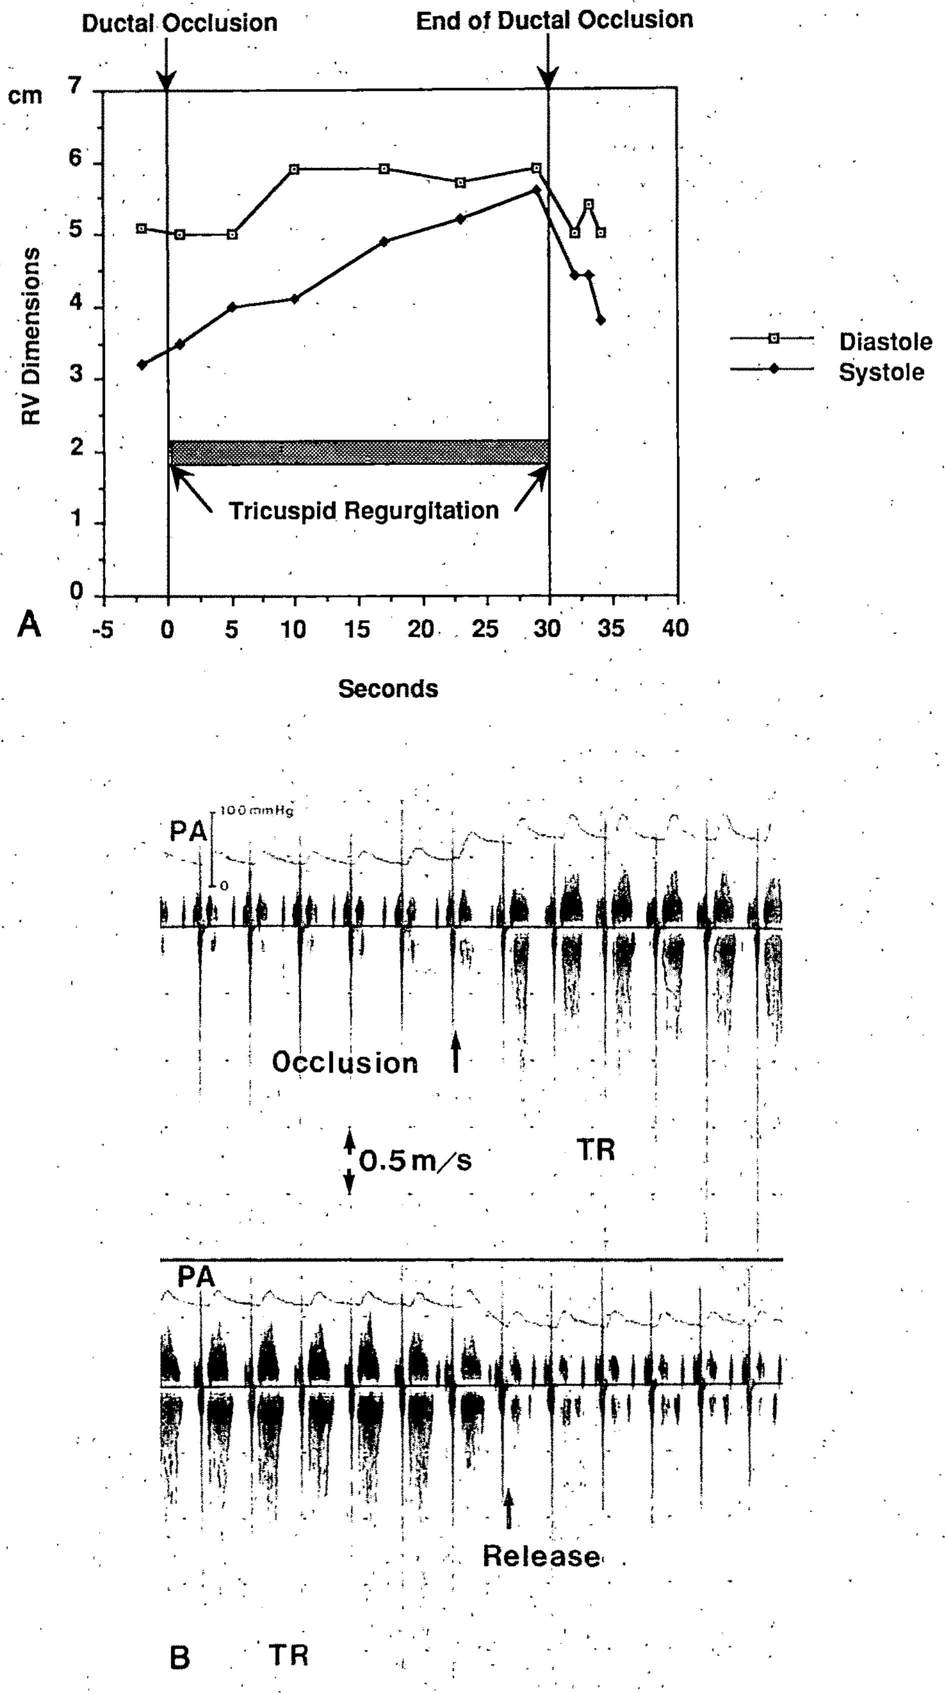

Fig. 2. Time course of fetal ductal occlusion. **A,** Right ventricular *(RV)* dimension by M-mode echocardiography during occlusion shows reversible increase in systolic and diastolic dimensions. **B,** Continuous-wave Doppler echocardiogram of tricuspid valve regurgitation *(TR)*, with onset within two beats after ductal occlusion and resolution after release of occlusion. Pulmonary artery pressure *(PA)* changes with ductal occlusion are also shown. *m/s,* Meters per second.

degree the right ventricle is able to adjust to a long-term increased afterload and whether the tricuspid valve becomes competent again after right ventricular adaptation have yet to be determined.

Acute ductal occlusion led to right ventricular dilatation and to a decreased right ventricular shortening fraction. These findings were easily recognizable during two-dimensional echocardiography. It is possible to diagnose ductal constriction in the human fetus; however, there has never been a documented case of ductal occlusion occurring in a human being. Whether decreased right ventricular shortening is a sign of ductal constriction and not occlusion has yet to be determined.

We concluded that immediate tricuspid regurgitation after acute ductal occlusion was reversible and appeared to be caused by right ventricular pressure increase rather than by ventricular dilatation. Major redistribution of flow occurred during fetal ductal occlusion, with an increase in left ventricular output and a decrease in right ventricular output. A dramatic change in right ventricular diameter and right ventricular shortening fraction accompanies fetal ductal occlusion.

Prognostic value of CA 125 and neopterin in women with ovarian cancer undergoing second-look laparotomy

To the Editors: We have read the article by Hunter et al. (Hunter VJ, Daly L, Helms M, et al. The prognostic significance of CA 125 half-life in patients with ovarian cancer who have received primary chemotherapy after surgical cytoreduction. AM J OBSTET GYNECOL 1990;163:1164-7) describing prolonged overall survival in patients with CA 125 half-life <20 days. The authors pointed out that after negative second-look procedures, "eight individuals whose serum CA 125 value normalized by 65 days after initial operation appeared to have improved survival." On the basis of a recent investigation,[1] we would like to extend the discussion raised by the authors.

We have determined serum concentrations of CA 125 and urine levels of neopterin immediately before second-look laparotomy in 72 women with ovarian cancer. Neopterin is a sensitive marker of cell-mediated immune activation.[2] One-year survival rates (mean ± SE) after surgical reexploration were associated ($p < 0.0001$) with concentrations of CA 125 (93% ± 4% in women with CA 125 values <35 U/ml; 47% ± 13% in women with higher CA 125 values) as well as neopterin (88% ± 5% in women with neopterin values <235 μmol/mol creatinine; 27% ± 13% in women with higher neopterin values).

Multivariate analysis was done to assess whether both predictors were independent of the surgical findings at second look, and separate survival curves were obtained by subdividing the group according to second-look outcome. CA 125 serum levels showed a stronger direct correlation than neopterin with the surgical findings at the procedure but failed to reach joint significance in addition to surgical outcome. In contrast, a significant correlation of raised neopterin levels with more unfavorable prognosis was found in patients with no evidence of disease and in those with residual tumors <1 cm. Women with tumors >1 cm uniformly had poor prognoses, as did patients with low versus high neopterin levels.

Identification of patients with negative second-look laparotomies who are at higher risk of disease progression would be helpful in ovarian cancer follow-up. Our results suggest that CA 125 provides an excellent predictor of the findings at second-look operation but does not provide predictive information for further follow-up in addition to the surgical outcome. In contrast, neopterin concentrations (which show a weaker correlation with the outcome of second look) do provide independent prognostic information and may be used to define risk groups. Our results are compatible with the background of both markers: whereas CA 125 is a classic tumor marker, neopterin is an indicator of cell-mediated immune activation and thus contributes information about a mechanism different from instantaneous tumor progression.

Response declined

Free β-protein studies need confirmation

To the Editors: I was impressed by the article of Macri et al. (Macri JN, Kasturi RV, Krantz DA, et al. Maternal serum Down syndrome screening: Free β-protein is a more effective marker than human chorionic gonadotropin. AM J OBSTET GYNECOL 1990;163:1248-53). However, the following month an advertisement appeared in my mail over the senior author's signature and from his *commercial* laboratory. It extolled free β-protein as a "patent pending scientific discovery" that "is the most accurate and reliable biochemical marker for Down's syndrome screening," citing this article by Macri et al.

The JOURNAL asks potential authors about conflict of interest, and this appears to be an example of significant "commercial association of the author." In my view, the findings of Macri et al. should be quickly confirmed by an independent investigator.

Robert C. Goodlin, MD
Department of Health and Hospitals, City and County of Denver, 777 Bannock St., Denver, CO 80204-4507

Reply

To the Editors: Dr. Goodlin is aware that it is conventional in clinical investigation to subject an original scientific discovery to retrospective studies, to publish these findings after peer review, and thereafter to undertake prospective studies. A careful reading of what Goodlin refers to as "an advertisement" reveals that it is actually a letter calling for participation in a prospective study. The letter states: "The discovery has been reduced to practice in an assay system and clinical reporting protocol for *investigational* Down syndrome screening" (emphasis added). Indeed, our Research Division has placed announcements concerning requests for proposals in major journals of obstetrics to advance additional free β-protein research and development.

We object to Goodlin's implication of conflict of interest in our publication of the effectiveness of free β-protein as a marker for Down syndrome. All original scientific contributions emanating from the Research Division of NTD Laboratories, Inc., have been clearly identified as such; the present case is no exception. Surely Dr. Goodlin would not suggest that research scientists with an explicit commercial association be denied the privilege of publication in the professional scientific literature or the benefits derived from peer review of original findings.

Value of high and low maternal serum α-fetoprotein levels in screening singleton pregnancies

To the Editors: Milunsky et al. reported an important prospective study to establish the overall benefits of high, low, and normal maternal α-fetoprotein levels in screening singleton pregnancies (Milunsky A, Jick SS, Bruell CL, et al. Predictive values, relative risks and overall benefits of high and low maternal serum α-fetoprotein screening in singleton pregnancies: New epidemiologic data. AM J OBSTET GYNECOL 1989;161:291-7). We read with great interest this fundamental study, and we wish to comment on the relationship of high maternal serum α-fetoprotein levels and the incidence of fetal chromosome defects. In their Table I they have reported one chromosome anomaly associated with a high maternal serum α-fetoprotein level. In contrast, in their hierarchical Table III this case has not been reported. Furthermore, in their Table IV no probabilities for chromosome defects were given in relation to high maternal serum α-fetoprotein levels.

In our opinion chromosome disorders are hierarchically top-ranking obstetric events. Moreover, the possible relationship of high maternal serum α-fetoprotein levels and chromosome defects has attracted the scientific attention of several studies.[1, 2] If we consider the one case of chromosome disorder in the 530 cases of high maternal serum α-fetoprotein levels (Table I), then the risk for a woman with a high maternal serum α-fetoprotein level of carrying a fetus with a chromosome defect is 1 in 530. This incidence, without any adjustment for maternal age, fetal structural defects, and amniotic fluid α-fetoprotein levels, is comparable to the incidence of Down syndrome in live-born infants of woman 34 years old.[3]

We believe that this part of maternal serum α-fetoprotein screening needs more clarification.

Demetrios Minaretzis, MD, and Christina Tsionou, MD

Reply

To the Editors: We appreciate the detailed reading of our article by Minaretzis and Tsionou, who correctly noted that the single chromosome anomaly reported in Table I is not shown in the hierarchical Table III. Further attention to the table footnotes would clarify their concern. The single chromosome anomaly has been incorporated in the neural tube defect group in the hierarchical table, each case being recorded only once, with neural tube defects taking precedence in being listed first. Table IV reflects this hierarchical tabulation as well and, hence, yielded no calculable odds for chromosome defects in this study in association with high maternal serum α-fetoprotein levels. Clearly, chromosome defects in the absence of any leaking lesions, such as spina bifida, omphalocele, and cystic hygroma, are very uncommon indeed. This observation is in line with those of others who have published on this association.

If Minaretzis and Tsionou wish to extrapolate from our data that 1 in 530 women had a chromosome defect, so be it. This figure would not come close to any standard recommendation for amniocentesis for prenatal genetic studies. In essence, fetal chromosome defects and raised maternal serum α-fetoprotein levels are a very infrequent association.

Laparoscopic ventrosuspensions

To the Editors: I read with great interest the article by Yoong (Yoong AFE. Laparoscopic ventrosuspensions. AM J OBSTET GYNECOL 1990;163:1151-3). This point has been a concern of ours, and our team is quite used to uterine retroversion and its treatment.[1] Our results are better than Yoong's, perhaps because of the selected cases with which we deal. I have two questions: (1) Dr. Yoong does not specify whether uterine retroversion was observed in each case. (2) There is no mention of pelvic varices in Table III. Is this because none were sought?

Laparoscopic ventrosuspension is effective in treating severe dyspareunia and chronic pelvic pain. If the cause of the pain is anatomic, the efficacy of the procedure is more important in selected women.[1] To say that this procedure "does not appear to be helpful" seems excessive.

B. Cristalli, MD

Reply

To the Editors: It seems unlikely that any gynecologist would antevert an already anteverted uterus. The association between pelvic varicosities and pelvic pain is well known; had pelvic varicosities been seen, they would have been reported. Pelvic venography is necessary to confirm ovarian vein dilatation and slowed clearance of dye from the pelvis.[1, 2]

Analysis of the data collected did *not* prove the efficacy of the procedure: At least 53.5% of the women in the study felt no better 6 months after laparoscopic ventrosuspension. Gleeson and Gaffney[3] reached a similar conclusion.

Laparoelytrotomy: Abdominal delivery without uterine incision

To the Editors: According to Garrigues,[1] extraperitoneal approach to the vagina to perform a cesarean section without a uterine incision was first proposed by Joerg in 1806. Several different modifications have been proposed and presented since then.[2, 3]

Under certain circumstances laparoelytrotomy may be inadvertently or, rarely, intentionally performed instead of a low-segment uterine cesarean section.[4] Goodlin[3] reported one intentional and four incidental laparoelytrotomies performed at Nebraska University Hospital in 1982. Our letter reports an incidental case of laparoelytrotomy.

A 23-year-old primigravid woman was at term and had been in the second stage of labor for approximately 3 hours with no analgesics. The vertex remained at 0 station in the left occipitotransverse position for 1½ hours. In the first stage of labor, when the cervix was dilated to 6 cm and 90% effaced, amniotomy had been performed.

The patient underwent a cesarean section because of the indication of cephalopelvic disproportion. With the patient under general anesthesia, the peritoneal cavity was entered. After the bladder flap was deflected downward and retained with a symphysis retractor, a low-transverse uterine incision was made and a 3700 gm male infant in good condition was delivered through the incision without difficulty. At the time of the incision we did not realize that the vagina rather than the lower uterine segment was being entered. When we tried to close the incision, we noted that the cervix was about 0.5 cm above the vaginal incision. The amount of bleeding was normal, and the only complication was a 0.5 cm laceration on the bladder wall with an intact bladder mucosa. This was easily repaired with 2-0 Dexon sutures. The patient was placed on a regimen of antibiotics, penicillin G procaine 800,000 U twice a day intramuscularly and gentamicin 80 mg three times a day intramuscularly.The urethral catheter was in place for 5 days. Patient and infant were discharged in good condition on the seventh postoperative day.

There is a tendency toward longer second stages of labor and avoidance of midforceps delivery. Cesarean sections after long second stages usually have higher morbidity than cesarean sections in uncomplicated cases. Cases like ours should be emphasized and discussed more in the literature so that complications can be decreased.

As Goodlin[3] mentioned, for the abdominal-vaginal approach to be effective, the cervix should be completely dilated, elevated, and retracted. The fetal vertex should be in the vagina and the vesicouterine fold should be freed further downward than in conventional cesarean sections. After the bladder is completely retracted, the vagina has a characteristic ballooned, shiny appearance.

If there is any doubt about landmarks, the fetus should be approached through the lower uterine segment through an incision on the upper side.

Another point is whether the scarred vagina may rupture or become an obstacle to labor. Further knowledge and discussion are necessary in this subject. A technically advanced laparoelytrotomy may become an alternative to conventional cesarean sections under certain circumstances.

Prenatal prediction of Down syndrome

To the Editors: O'Brien et al. (O'Brien W, Knuppel R, Torres C, Sternlicht D. Potential prenatal predictions of Down syndrome: A statistical analysis. Am J Obstet Gynecol 1990;163:1796-8) showed that α-fetoprotein, human chorionic gonadotropin, and biparietal diameter/femur length ratio all are sufficiently independent to be used in combination for prenatal prediction of Down syndrome. This requires the use of multivariate gaussian statistics,[1] which have the property that any inaccuracies are multiplied. We statistically examined the screening data of 4605 women routinely screened for fetuses with Down syndrome. There were 2834 complete data sets: age at estimated date of confinement, last menstrual period, biparietal diameter (outer-to-outer table), femur length, α-fetoprotein, human chorionic gonadotropin, and blood sample collected on the same day as ultrasonographic scan.

We demonstrated, using ultrasonographic dating of gestational age expressed as weeks' gestation, that the true calculated risk based on two parameters (α-fetoprotein and human chorionic gonadotropin) may lie anywhere in the range 78% to 152% of the actual calculated risk (analytic errors ignored). Similarly, by use of three parameters (α-fetoprotein, human chorionic gonadotropin, and urinary estradiol), the true risk may lie in the range 40% to 250% of the actual risk (unpublished data). These errors are important because they may result in an incorrect decision about the requirement for amniocentesis and also because they are avoidable. The error is caused by the conversion of a relatively precise measure of fetal development (biparietal diameter) into an imprecise measure (weeks' gestation). Basing gestational age on last menstrual period also is not precise enough because of poor recall by patients and variability of menstrual cycle length.

O'Brien et al. showed a trend for biparietal diameter/femur length ratio to decrease between 15 and 18 weeks' gestation. However, they only provided details of the ratio by week of gestation. If biparietal diameter/femur length ratio is to be of use in screening, errors resulting from gestation dating must be avoided as far as possible; therefore we examined the relationship between the ratio and gestational stage assessed by raw biparietal diameter value and by ultrasonographically derived weeks' gestation. We also found a trend in ratio relative to weeks' gestation, but we found that at the edges of the biparietal diameter size band there were significant deviations from the ratio derived by using weeks' gestation to define fetal age.

We believe that using actual biparietal diameter and not biparietal diameter–derived weeks' gestation for assessment of gestational age will decrease edge effects, thereby improving the precision of data used to calculate risk. This should significantly improve screening for Down syndrome–associated pregnancy by reducing false-positive and false-negative screening results. Therefore we suggest that, instead of using week-based medians for determining expected biparietal diameter/femur length ratio, the following linear regression parameters (product moment) such that biparietal diameter/femur length ratio = A + (Biparietal diameter × B) should be used ($A = 1.97997$; $B = -0.0080335$; $r = -0.202$).

Reply

To the Editors: I appreciate the interest the readers have demonstrated in our study and am pleased to see that their findings are similar to ours. I agree with the difficulties encountered in the use of multivariate gaussian statistics and agree that conversion of biparietal diameter (or femur length) measurements to gestational age assessment results in a loss of precision.

This conversion, however, allows consideration of several recent parameters in the same framework as the well-established reporting of α-fetoprotein. I suspect that, in spite of the mathematical superiority of computational values, as pointed out by the readers, practical consideration will lead to the use of weekly medians, as has occurred with α-fetoprotein testing.

Is opposition to abortion unethical?

To the Editors: The "obstetric ethic" described by Chervenak and McCullough in the November 1990 issue of the JOURNAL (Chervenak FA, McCullough LB. Does obstetric ethics have any role in the obstetrician's response to the abortion controversy? AM J OBSTET GYNECOL 1990;163:1425-9) justifies abortion on demand before fetal viability by excluding any opposing arguments that are based on religious traditions.

Recently, however, a leading bioethicist noted that the biomedical ethics debate has been impoverished by the a priori exclusion of arguments that are based on various religious traditions.[1] In fact, all arguments for and against unrestricted abortion are based on fundamental presuppositions of some type. Whether they are religious is irrelevant.

My question to the authors of this Clinical Opinion is, in light of the fundamental presuppositions of their "obstetric ethic," is it unethical for an obstetrician to oppose the current practice of abortion on demand?

Steve Calvin, MD

5806 Oakland Ave. S., Minneapolis, MN 55417

REFERENCE

Reply

To the Editors: Dr. Calvin uses a phrase that is used commonly in the abortion controversy but also has many meanings. "Abortion on demand" can mean that a physician is obligated to perform an abortion even if doing so, for whatever reason, violates the physician's private conscience. We argue explicitly that there is no such ethical obligation. Moreover, we point out that religious traditions are a primary influence on the formation of private conscience. Thus we can in no way be understood to exclude altogether religious traditions from obstetric ethics.

There is a second sense of "abortion on demand"—a phrase we do not use because we find it useless—that means that there can be no objections to abortion because the fetus never had moral status. We argue that the fetus does indeed sometimes have the moral status of being a patient. Hence we would reject "abortion on demand" in this second sense of the phrase.

In answer to Dr. Calvin's question, we stated that, either for reasons of private conscience or when the fetus is a patient, any obstetrician should have grave moral reservations about "abortion on demand" in the above two senses.

There is yet a third sense of "abortion on demand," namely, that pregnant women should be free to withhold, confer, or, having once conferred, withdraw the moral status of being a patient on the previable fetus. In effect, our article defends this sense of "abortion on demand," even while rejecting the previous senses of the phrase.

Examination of placentas by pathologists

To the Editors: The opinions expressed by Salafia and Vintzileos (Salafia CM, Vintzileos AM. Why all placentas should be examined by a pathologist in 1990. AM J OBSTET GYNECOL 1990;163:1282-93) represent wishful thinking regarding the ability of a pathologist's examination of the placenta to give meaningful information not better obtained by clinical means.

In the comment section of their article they imply that examination of the placenta can "identify the exact cause" of an untoward outcome of pregnancy. However, numerous studies, including a major contribution among their own references, have emphasized the relative nonspecificity of pathologic examination, both gross and microscopic.[1] On the contrary, the experienced pathologist knows the disappointment of reporting, for example, severe chorioamnionitis by microscopy to a colleague, only to learn that the product of the suspect pregnancy was a bouncingly healthy neonate.

Furthermore, their Table IV lists findings and their respective possible causes, for which one can easily suggest superior clinical or laboratory means to make the diagnosis.

Finally, I find their cost-effectiveness argument quite unconvincing: To generate a charge of $2 million as prophylaxis against a possible $5 to $6 million lawsuit is not powerful leveraging. A cost of $225 per placenta for useless information is unconscionable in this time of diminished medical resources and merely buys the obstetrician a false sense of added security.

Howard Goldman, MD

Department of Pathology, Merrithew Memorial Hospital, 2500 Alhambra Ave., Martinez, CA 94553

REFERENCE

1. Fox H. Pathology of the placenta. In: Bennington JL, ed. Major problems in pathology. Philadelphia: WB Saunders, 1978 vol 7.

Reply

To the Editors: Unfortunately Dr. Goldman has missed our point. This is evident from his first paragraph. We did not represent placental pathologic examination to stand independent of, separate from, or as a substitute for clinical means of obstetric assessment. We instead emphasized that a pathologist requires clinical information to understand the relevance of placental lesions to outcome. Referencing a text does not require that we accept all its tenets, and we have significant disagreements with Dr. Fox in many areas. We are amazed that Dr. Goldman could be disappointed by reporting severe chorioamnionitis in the face of a "bouncingly healthy" neonate. Acute ascending infections may have a multiplicity of effects in the fetus-neonate that are remote from sepsis. The pathologist and the obstetrician should communicate on each case; the obstetrician should recognize that subclinical chorioamnionitis caused fetal distress,[1, 2] which led to intervention and, thankfully, a healthy newborn. Only then will the pathologist recognize that chorioamnionitis may be clinically significant in the absence of infectious morbidity or mortality. Dr. Goldman apparently fails to consider that a healthy newborn does not of necessity grow up to be a neurologically normal child. As we cited, 85% of cases of mental retardation have no scientific or clinically based explanation.[3] Experimental and clinical studies have shown that both acute intraamniotic infection and chronic villitis representing a potential congenital viral infection can be related in a causal fashion to long-term neurologic impairment.[4,5] More than 75% of histologically evident intraamniotic infection ("chorioamnionitis") and >95% of cases of chronic villitis are clinically silent, we submit that the "usefulness" of the information derived from placental pathologic examination will be minimal if the only outcome variable to be considered is the level of neurologic function at birth. In this discussion we also indirectly addressed the issues raised in the third paragraph. Chronic villitis, hemorrhagic endovillitis, infarcts, and other villous pathologic conditions cannot be definitely assessed by any modality other than placental examination. We stand by our assertion that placental examination *may* identify the exact cause of poor pregnancy outcome. Finally, we agree that the cost of placental pathologic examination, if the information is not combined with the obstetric clinical data, is indeed unconscionable. Placental pathologic examination cannot be considered to be separate from, or a substitute for, clinical assessment and only achieves its optimal returns when utilized in concert with clinical and laboratory investigations. Our article was born of the realization that the unique benefits we obtained from placental examinations in our institution were derived from our communications and interactions on the obstetrics floor, in the delivery suite, and at morbidity and mortality reviews.

We thank Dr. Goldman for his comments. He has permitted us to restate, perhaps more strongly, the need for *informed* examination of the placenta, informed by clinical information and by collaboration with obstetric colleagues.

Maternal genital herpes and gender of offspring

To the Editors: In their Letter to the Editors McGregor and Leff (McGregor JA, Leff M. Does maternal genital herpes infection influence fetal gender? AM J OBSTET GYNECOL 1990;162:1346-7) suggest that there is a decreased proportion of male infants born to mothers with a history of genital herpes complicating pregnancy. This caused us to review the data from our cohort of pregnant women with symptomatic and asymptomatic genital herpes at the University of Washington. Among women with herpesvirus type 2 type-specific antibodies, as detected by Western blot analysis, we demonstrated a normal male/female ratio of their offspring (Table I).

Table I. Maternal herpesvirus serologic results and gender of offspring ($N = 2084$)

Infants	*Seronegative*	*Herpesvirus type 1*	*Herpesvirus type 2*	*Herpesvirus types 1 and 2*
Male	234 (50.6%)	503 (50.9%)	169 (53.7%)	162 (50.8%)
Female	228 (49.4%)	485 (49.1%)	146 (46.3%)	157 (49.2%)

$\chi^2 = 0.87$; $p = .83$.

Table II. Maternal herpesvirus history and gender of offspring ($N = 2041$)

Infants	*No history*	*Herpesvirus before pregnancy*	*Herpesvirus during pregnancy*
Male	943 (51.7%)	86 (48%)	21 (53.8%)
Female	880 (48.3%)	93 (52%)	18 (46.2%)

$\chi^2 = 0.97$; $p = 0.61$.

Similarly, in this same cohort, when we calculated the percentage of male infants on the basis of the clinical history rather than serologic results, again there was no alteration in the normal male/female ratio among offspring (Table II).

Zane Brown, MD, and Larry Corey, MD
Division of Maternal-Fetal Medicine, Department of Obstetrics and Gynecology, RH-20, University of Washington School of Medicine, Seattle, WA 98195

Reply

To the Editors: My colleagues and I are pleased that Brown and Corey have answered our question in their uniquely well-described population. As noted in our letter, others have described fetal and newborn gender differences among women with proven or possible perinatal infectious processes in a variety of settings; male gender consistently predisposes to perinatal infection in studies going back decades.[1-3] MacGillivray and Davey[3] noted convincingly higher rates of preterm birth and premature rupture of membranes among South African women giving birth to male infants. Conversely, in a recent analysis of 8758 births at the University of Colorado, similar risks of preterm premature rupture of membranes, clinical chorioamnionitis, and postpartum endometritis were found in women giving birth to male and female infants.[4] These contrasting findings suggest that male gender–linked predispositions to perinatal infection are most likely to be expressed in women at high risk for reproductive tract infections before or during pregnancy. Controlled studies of possible interactions of reproductive tract infection, fetal gender, and the pathologic characteristics of parturition are required to fully examine such suggestions. My colleagues and I thank Brown and Corey for their observations.

Correction

In the article by Weiner et al., entitled "The therapeutic efficacy and cost-effectiveness of aggressive tocolysis for premature labor associated with premature rupture of the membranes" (AM J OBSTET GYNECOL 1988;159:216-22), in Table V on page 219, the second major heading in the left-hand column was omitted. The correct table is shown here.

Table V. Comparisons by selected intervals

	Bed rest (%)	*Tocolysis (%)*
From membrane rupture to delivery		
<24 hr	7.1	6.1
<48 hr	23.8	12.1
<72 hr	38.1	30.3
From onset of regular contractions to delivery		
<24 hr	42.1	24.1
<48 hr	63.2	55.1
<72 hr	71.1	62.1

All differences nonsignificant.

DIRECTOR OF MATERNAL-FETAL MEDICINE

Albert Einstein Medical Center (AEMC), a 600+ bed tertiary care teaching hospital, is seeking a board certified maternal-fetal medicine subspecialist as Director of the Division of Maternal-Fetal Medicine to develop and direct the comprehensive perinatal program in this institution. AEMC is a major referral center in north Philadelphia supporting numerous post-graduate medical education programs, including a fully accredited residency program in obstetrics and gynecology. The Department of Obstetrics and Gynecology has a long-standing tradition of excellence in health-care delivery and supports a variety of clinical research and educational activities. The Division of Maternal-Fetal Medicine serves as a tertiary referral center within the metropolitan Philadelphia area. Its service includes maternal intensive care unit, maternal transport program, high risk obstetrics, genetic counseling, diagnostic genetic procedures (amniocentesis, CVS, cordocentesis). targeted (level II) obstetrical ultrasound and comprehensive antenatal fetal surveillance. Our Department is supported by a Level III NICU and a Cytogenetic Laboratory. There is a strong institutional support and emphasis in research with funds and laboratory space available for basic research. A construction project is under way for a new labor and delivery suite and a comprehensive fetal diagnostic center. We are also planning to develop a maternal-fetal medicine fellowship training program with Temple University.

AEMC is a major affiliate of Temple University. Academic appointment is available for all full-time AEMC faculty. Highly competitive salary and very attractive fringe benefits are included. If you are interested in this position or would like additional information about this unique opportunity, please write to *Sze-ya Yeh, M.D., Chairman, Department of Obstetrics and Gynecology, Albert Einstein Medical Center, 5401 Old York Road, Klein #410, Philadelphia, PA 19141.* Telephone **(215) 456-6993,** FAX **(215) 456-6271.**

OBSTETRICS & GYNECOLOGY CHICAGO, IL

Well established, prominent eight physician OB/GYNE practice with two growing offices in Downtown Chicago and affluent suburb seeks BE/BC physician. In-office procedures include ultrasound, fetal monitoring, amniocentesis, colposcopies, and mammography. THE SECOND INTERNATIONAL SYMPOSIUM ON GYNECOLOGIC SURGERY AND ADHESION PREVENTION

Ocean Grand Hotel, Palm Beach, Florida • January 31 - February 2, 1992

The Second International Symposium on Gynecologic Surgery and Adhesion Prevention is designed to bring together the latest advances in research, clinical technologies and therapies in this exciting field. The focus of the meeting will be the **prevention of post surgical adhesions in gynecological surgery.**

Presenters, moderators and panelists from around the world have been selected based on their clinical experience and research expertise. The symposium is supported by an educational grant from **Ethicon, Inc.**, and is sponsored by Symposia Medicus, a non-profit corporation for continuing medical education.

SUBJECT AREAS TO BE PRESENTED AND DISCUSSED INCLUDE:

- Ovarian Surgery
- Intrauterine Surgery
- Surgical Techniques and Their Impact on Adhesions
- Laparoscopic Surgery
- Laser Surgery
- Clinical Studies on Adhesion Prevention

PROGRAM PLANNING COMMITTEE

Michael P. Diamond, M.D., Yale Univ. Sch. of Med., Dept. of OB/GYN, New Haven, CT
Gere S. diZerega, M.D., Univ. of So. CA Sch. of Med., Dept. of OB/GYN, Los Angeles, CA
Robert L. Reid, M.D., Queens Univ., Dept. of OB/GYN, Kingston, Ontario, CN
Cary B. Linsky, Ph.D., Ethicon, Inc., Somerville, NJ

For further information regarding symposium registration/brochure, contact:
Symposia Medicus, 1299 Newell Hill Place, Suite 301, Walnut Creek, CA 94596-5220

The department of Obstetrics and Gynecology at the University of Tennessee College of Medicine is actively recruiting a full-time Perinatologist for its Division of Maternal/Fetal Medicine. The teaching hospital serves as the Tertiary Care Center for 80 counties in West Tennessee, East Arkansas, North Mississippi, Southern Missouri and a part of Kentucky; an area with approximately 40,000 deliveries per year. About 50% of the pregnancies delivered at the center are high risk pregnancies. Perinatal services each year include over 20,000 outpatient visits, 7,800 deliveries and over 1,400 patients seen in Reproductive Genetics. Excellent opportunity to participate in teaching in a Board-approved fellowship program and collaborate in ongoing research in clinical Perinatology. Critical Care in Obstetrics, Ultrasound and Prenatal Diagnosis. Board eligibility/certification in Maternal/Fetal Medicine is required. Interested candidates should send curriculum vitae to: Baha M. Sibai, M.D. Division of Maternal/Fetal Medicine University of Tennessee, Memphis 853 Jefferson Avenue, Rm. E-102 Memphis, TN. 38103 (901) 528-5660 The University of Tennessee, Memphis is an equal employment opportunity/affirmative action/Title IX/Section 504 employer/ADA Employer

---

The Department of OB/GYN at the Washington Hospital Center is currently seeking another full time Perinatologist for their Division of Maternal Fetal Medicine to work with the Director of Obstetrics/Maternal Fetal Medicine.

The Washington Hospital Center is a 900 bed tertiary care teaching facility with a compliment of 16 residents in the Department of OB/GYN. Currently the Department of OB/GYN delivers approximately 3,000 babies annually and because of its urban setting, the incidence of high risk pregnancies is approximately 40%.

There is an active Antepartum Surveillance unit and Prenatal diagnostic unit with OB/GYN ultrasound lab available in the division of Maternal Fetal Medicine. Invasive prenatal diagnostic procedures are performed in the division.

Excellent opportunity for active clinical research and resident teaching. We are interested in applicants who are qualified in Maternal Fetal Medicine, board eligible/board certified. Experience in OB/GYN Ultrasound and invasive prenatal diagnostic testing preferred.

Salary is commensurate with qualifications and experience.

Please send a Curriculum Vitae to Dr. Shailini Singh, Director, Obstetrics/Maternal Fetal Medicine, Washington Hospital Center, 110 Irving Street, NV, Suite 5W40, Washington, DC 20010 or Fax to 202/877-6590.

ONCOLOGY

Gynecologic oncologist wanted to develop a division of gynecologic oncology supported by a newly completed regional cancer center and the West Virginia University School of Medicine. Responsibilities will include faculty recruitment, education, development of regional programs in prevention and treatment of gynecologic malignancy. The deadline date for receipt of applications is November 1, 1991.

OB/GYN Subspecialists

Gynecologic Oncology
Perinatology
Reproductive Endocrinology
Urogynecology

The University of South Dakota School of Medicine currently has openings for BE/BC Obstetric/Gynecologic subspecialists.

These are full-time academic positions ideally suited for the clinician scholar who wishes to develop and guide a program which will have a significant impact on women's health care. Although our program is heavily slanted toward medical student education and patient care, the department encourages and provides ample resources for clinical and laboratory research.

Sioux Falls, included in David Frankes' book, America's Fifty Safest Cities, has a strong economic base, growing population and a progressive educational system. South Dakota's four season climate welcomes endless recreational activities year-round.

Competitive financial packages offered. EOE/AAE.

MATERNAL FETAL MEDICINE
UNIVERSITY of VERMONT

The Division of Maternal Fetal Medicine at the University of Vermont has an opening for a 4th Board Certified/Eligible perinatologist.

The Medical Center Hospital of Vermont serves as the tertiary care center for Vermont and Northeastern New York with a busy clinical service. Responsibilities include both hospital and ambulatory patient care, genetic services, and teaching combined with protected research time. There is an active research division with the opportunity for both clinical and basic science research with both large and small animal facilities. Recruitment is for Assistant/Associate Professor with interests in research and teaching. The Maternal Fetal Medicine Division also offers a 3 year Fellowship Program.

We are an equal opportunity/affirmative action employer and encourage women and people from diverse racial, ethnic, and cultural backgrounds to apply. Applications will be accepted until the position is filled.

Please send Curriculum Vitae to:

Eleanor L. Capeless, MD
Director, Maternal Fetal Medicine
Dept. of Ob/Gyn
Medical Center Hospital of Vermont
Burlington, VT 05401

Faculty Positions

Gynecologist

Our energetic, progressive and cooperative Gynecology Division has an opening available July 1, 1992. Rank is open. The position may be either tenure or clinical track and carries a 70% clinical and 30% professional development time-share. Call is shared with University-based academic faculty.

This department has facilities for colposcopy, laser, urogynecology, geriatric gynecology, and would be willing to establish facilities for other interests. Potential also exists to develop educational activities in clerkship, programs for residency or CME. An obstetrical practice may be established but is optional

Ob-Gyn Generalist

Immediate opportunity for the University satellite clinics within the city of Madison. Rank is open. This position is 90% clinical with 10% of time protected for academic activities. Clinic facilities are new, well-equipped and have ready access to University Hospital and all its services. Physicians will be nontenure track faculty and evaluated on the clinical and teaching activities.

In addition to general obstetrics and gynecology, opportunities exist in geriatric gynecology, colposcopy, urodynamics, laser and other modalities. Call shared with other University faculty. Generous vacation and benefits are provided.

Interested and qualified candidates are invited to reply to:

THE DEPARTMENT OF OBSTETRICS AND GYNECOLOGY
UNIVERSITY OF WISCONSIN MEDICAL SCHOOL

is seeking applicants for four (4) full-time faculty positions for a new women's health center and academic program at its Milwaukee Clinical Campus.

Sinai Samaritan Medical Center has recently consolidated its obstetrical and gynecological services in a redesigned facility in downtown Milwaukee. The department supports a residency program, the largest perinatal service in Wisconsin (5500 deliveries), consultative ultrasound, genetic and infectious disease programs, and reproductive/endocrine services (including an IVF program). The department is affiliated with Planned Parenthood of Wisconsin and St. Luke's Medical Center in Milwaukee.

Qualifications include board candidacy or certification in obstetrics and gynecology and a commitment to teaching residents, medical students, and clinical research. Qualifications for the four positions for GENERAL OB/GYN can take into consideration special individual interests. Special expertise of interest for the department are:

- STATEWIDE FAMILY PLANNING AND AMBULATORY CARE (Part-time medical director, Planned Parenthood)
- OPERATIVE LAPAROSCOPY, HYSTEROSCOPY
- UROGYNECOLOGY
- RESIDENCY/MEDICAL STUDENT EDUCATION
- OB/GYN ULTRASOUND

Private practice opportunities are also available in an associated offsite multispecialty clinic and all faculty members participate in a group practice at the institution. Contact:

New 2nd Edition!

COMPREHENSIVE GYNECOLOGY

Arthur L. Herbst, M.D.; Daniel R. Mishell, Jr., M.D.; Morton A. Stenchever, M.D. and William Droegemueller, M.D.

- Provides increased coverage of perimenopausal and postmenopausal topics and improved coverage of dysfunctional uterine bleeding.
- Key Words and Key Points allow the reader a quick overview of the content in each chapter.
- An excellent review tool and/or daily reference -- for use alone or paired with COMPREHENSIVE GYNECOLOGY REVIEW by Holzman et. al.

December 1991. Approx. 1,184 pages, 129 ills. (Book Code: 06244)

New 2nd Edition!

COMPREHENSIVE GYNECOLOGY REVIEW

Gerald B. Holzman, M.D.; Frank Wen-Yung, M.D.; Douglas Laube, M.D.; and Louis Vontver, M.D.

- Designed as a supplement to Herbst, COMPREHENSIVE GYNECOLOGY, 2nd edition, these two books create a comprehensive, up-to-date review package.
- Using a question/answer approach, this review book is the only one at present to so precisely mimic the contents of the ABOG Board Exams.

December 1991. Approx. 320 pages, 123 ills. (Book Code: 02279)

New!

A TEXT AND ATLAS OF INTEGRATED COLPOSCOPY

Malcom C. Anderson, F.R.C.Path., F.R.O.C.G.; J.A. Jordan, M.D., D.R.C.O.G.; A.R. Morse, C.F.I.A.C.; F. Sharp, M.D., F.R.C.O.G.

- Provides "how-to" information for effective use of the colposcope in diagnosis, treatment, and management of dysplasia.
- Extensive illustrations detail appearance of healthy and diseased cervix.

December 1991. Approx. 256 pages, 533 color illustrations. A Chapman and Hall publication. (Book Code: 21861)

REOPERATIVE GYNECOLOGIC SURGERY

David H. Nichols, M.D.; with 21 contributors.

- Addresses the appropriate diagnostic procedures, analysis of indications in timing, and the surgical approach in management of the patient requiring gynecologic re-operation.
- Presents precise descriptions of techniques.
- Contributors are well-recognized authorities.

1991. 348 pages, illustrated. (Book Code: 20353)

3rd Edition

CLINICAL GYNECOLOGIC ONCOLOGY

Philip J. DiSaia, M.D. and William T. Creasman, M.D.

- Features a new section on colorectal cancer plus expanded coverage of the Complications of Disease and Therapy section.
- The Tumor Immunology chapter has been revised to include new information on host defense mechanisms.

1989. 721 pages, 221 ills. including 32 in full color. (Book Code: 01513)

3rd Edition

BENIGN DISEASES OF THE VULVA AND VAGINA

Raymond H. Kaufman, M.D.; Eduard G. Friedrich, Jr., M.D., L.L.D.; and Herman L. Gardner, M.D.; with 9 contributors.

- Strong emphasis is placed on pathology as it relates to clinical problems.
- Describes the clinical features of the lesions and documents them with both microscopic and macroscopic illustrations.

1989. 476 pages, 450 ills. (Book Code: 20002)

THERAPEUTIC HYSTEROSCOPY: Indications and Techniques

Alvin M. Siegler, M.D., D.Sc.; Rafael F. Valle, M.D.; Hans J. Lindemann, M.D.; and Luca Mencaglia, M.D.

- Emphasizing technique with much improved instrumentation, it provides the step-by-step instruction you need to know to treat intrauterine disorders.
- Focuses on operative therapeutic techniques with a review of background information on standard uses for the hysteroscope.

1990. 255 pages, 231 ills. and 124 in color. (Book Code: 05504)

New!

- Encompasses general gynecology, reproductive endocrinology, pregnancy (including maternal complications, obstetrics, and fetal disorders), gynecologic oncology, and infertility.

1991. 325 pages. A Hanley & Belfus, Inc. publication. (Book Code: 01693)

New!

THE 1991 YEAR BOOK OF INFERTILITY

Daniel R. Mishell, Jr., M.D.; Rogerio A. Lobo, M.D.; and C. Alvin Paulsen, M.D.

October 1991. 300 pages, 60 ills. (Book Code: 22093)

New 2nd Edition!

ATLAS OF FEMALE INFERTILITY SURGERY

Robert B. Hunt, M.D.; with 31 contributors.

- Provides very detailed, "how-to" information for performing organ-preserving pelvic operations.
- Covers the specifics of procedures from incision and type of suture to use, to other practical aspects of treatment for infertile women.

December 1991. Approx. 464 pages, 624 ills. (Book Code: 22450)

New!

OFFICE GYNECOLOGY

Morton A. Stenchever, M.D.; with 13 contributors.

- Offers specific approaches to a variety of problems seen in the gynecologic office, emphasizing diagnosis and treatment.
- Covers organization of the office, approach to the patient, and the understanding of general health maintenance areas of care.

December 1991. Approx. 432 pages, 191 ills. (Book Code: 04817)

New!

MEDICAL DISORDERS DURING PREGNANCY

William M. Barron, M.D. and Marshall Lindheimer, M.D.; with 30 contributors.

- Offers specific guidance on techniques for diagnosis, treatment and follow-up.
- Each chapter focuses on a key category of medical illness with specific chapters covering hypertension and diabetes – common problems in pregnant women which differ from the same conditions in other patients.

1991. 661 pages, illustrated. (Book Code: 20371)

DIAGNOSTIC AND OPERATIVE HYSTEROSCOPY: A Text and Atlas

Michael S. Baggish, M.D.; Jacques Barbot, M.D.; and Rafael Valle, M.D.

- Demonstrates the wide range of clinical applicability for hysteroscopy.

1988. 360 pages, 532 ills. with 314 in color. (Book Code: 09628)

2nd Edition

LASER SURGERY IN GYNECOLOGY AND OBSTETRICS

William R. Keye, Jr., M.D.; with 19 contributors.

- Generously illustrated, this book represents the state-of-the-art in gynecologic laser surgery.
- Much of the book is devoted to laser treatment of disease to help you improve your skill with the laser of your choice.

1990. 304 pages, illustrated including 15 color plates. (Book Code: 20075)

New!

ANESTHETIC AND OBSTETRIC MANAGEMENT FOR HIGH-RISK PREGNANCY

Sanjay Datta, M.D., F.F.A.R.C.S.(Eng.); with 62 contributors.

- Emphasizes anesthesiologist/ obstetrician teamwork in the care of high-risk patients.
- Addresses the broad range of medical complications in high-risk pregnancy in chapters co-authored by an anesthesiologist and an obstetrician.

1991. 735 pages, 115 ills. (Book Code: 20390)

Diagnostic and Operative Hysteroscopy
A Text and Atlas
Laser Surgery in Gynecology and Obstetrics
CHILDBIRTH
YEAR BOOK

LEGAL PRINCIPLES AND PRACTICE IN OBSTETRICS AND GYNECOLOGY

Max Borten, M.D. and Emanuel A. Friedman, M.D.

- Addresses the critical medicolegal aspects affecting obstetrics and gynecology.
- Reports on the most frequent causes of liability claims in the specialty as well as issues of informed consent; prolapsed umbilical cord; anesthesia; ectopic pregnancy; failure to diagnose cervical cancer; and much more.

Volume 1: 1989. 320 pages + ills. (Book Code: 20003)
Volume 2: 1989. 352 pages + ills. (Book Code: 20161)

A COLOR ATLAS OF CHILDBIRTH AND OBSTETRIC TECHNIQUES

F.A. Al-Azzawi, M.B.Ch.B., M.A., Ph.D., M.R.C.O.G.

- Uses step-by-step, high quality photographs, diagnostic ultrasound images and line artwork to bridge the gap between the textbook and clinical practice.
- Emphasizes the practical management of obstetric techniques and relates descriptions directly to daily experiences on labor wards.

1991. 144 pages, 341 ills. with 144 in color. A Wolfe Publication. (Book Code: 06287)

Good People. Good Medicine.

THE DEPARTMENT OF OBSTETRICS AND GYNECOLOGY UNIVERSITY OF WISCONSIN MEDICAL SCHOOL

is seeking applicants for two (2) additional full-time faculty positions in MATERNAL FETAL MEDICINE for a new women's health center and academic program at its Milwaukee Clinical Campus. The current faculty includes two perinatologists.

Sinai Samaritan Medical Center has recently consolidated its obstetrical and gynecological services in a redesigned facility in downtown Milwaukee. The department has the largest perinatal service in Wisconsin (5500 deliveries) and has a dedicated antenatal testing and perinatal ultrasonography unit, a midwifery, and adolescent pregnancy service. The department has an affiliation with St. Luke's Medical Center in Milwaukee for its residency program.

Qualifications include board candidacy or certification in maternal-fetal medicine and a commitment to teaching residents, medical students, and clinical research. Competitive salary package. Contact:

OBSTETRICIAN/GYNECOLOGIST

Are you looking for a practice opportunity that offers unlimited potential and rewards? If you are, consider the options available with one of northwest Ohio's leading health care systems. We currently have several exciting practice opportunities available for board certified/board eligible OB/GYN's including solo, partnership, and group practices. Obstetrical referrals are also available from physicians who recently limited their practice to gynecology. For those physicians interested in teaching to augment their practice, precepting opportunities are also available in conjunction with one of our hospital-based family practice residency programs.

These opportunities offer an exceptional support package which includes a generous guaranteed salary, malpractice insurance, family health insurance and disability insurance, overhead expenses, moving expenses, and much more!

This area of the Great Lakes region offers a host of social, cultural, recreational, and sporting activities including several college and professional teams within a 50-mile radius.

For further details about these exciting practice opportunities, please send your curriculum vitae to: P.O. Box 2450, Toledo, Ohio 43606.

“Group Health has shown that quality care at a reasonable price is not an impossible dream.”

The New York Times, May 2, 1991

“Group Health is my model for the future.”

Arnold Relman, MD, retired editor,
New England Journal of Medicine

“Escalating malpractice costs make starting your own practice almost impossible. At Group Health, I earn a good salary and have time to enjoy it.”

Ronald Helm, OB/GYN
Tacoma Specialty Clinic

Group Health has been quietly revolutionizing health care since 1947. With the single premise that quality health care needn't be expensive, we've built one of the most respected managed care systems in America. Our physicians can concentrate their efforts on the practice of medicine without worrying about their next paycheck. This improves the relationship between doctor and patient, resulting in better health care.

Discover for yourself the future direction of health care. Call us toll-free at (800) 543-9323. Group Health is an equal opportunity employer.

Group Health Cooperative
of Puget Sound

CHAIR, DEPARTMENT OF OB-GYN

An 830-bed regional tertiary care teaching hospital is seeking a Chair for its Department of OB-GYN. The Allentown Hospital–Lehigh Valley Hospital Center has a fully-approved, free-standing OB-GYN Residency Program with two residents each year and trains a total of 70 residents and 400 medical students.

The hospital is a regional Level III Perinatal Center. Of over 3,000 births in 1990, 42 percent were in the high-risk category. The department is supported by a 20-bed Level III NICU managed by four full-time neonatologists.

In response to the continuing growth of the community and the expansion of the OB-GYN Department, the hospital will ask the new Chair to lead the search for the newly-created position of Vice Chair/Program Director of OB-GYN. The department is also awaiting the arrival of the new Chair to help in the search for a full-time perinatologist. (There are 33 active OB-GYN physicians on staff, including a gynecologic oncologist and reproductive endocrinologist.)

The hospital is a clinical campus of Hahnemann University in Philadelphia, where the new Chair will hold a Vice Chair appointment and an academic appointment at the rank of associate or full professor. The hospital is in Allentown, a burgeoning area in eastern Pennsylvania within close proximity of Philadelphia and New York City.

Candidates must be board certified with administrative experience and familiarity with both academic and community hospital environments. Interested candidates may write or call for information and send curricula vitae, in confidence, to: **Headley S. White, Jr., M.D., Sr. Vice President, Medical and Academic Affairs, c/o HealthSearch, 1243 S. Cedar Crest Blvd., Suite 3000, Allentown, PA 18103, (215) 821-3090.** Descriptive brochure available.

UTAH

A young, boarded group of three OB/GYN's in Layton, Utah is now seeking to add a fourth member to their successful practice. Their office is located next to our hospital that serves a population of 140,000.

The Wasatch Mountain range and its undisturbed natural environment serves as a scenic backdrop for this family-oriented community, located 15 miles south of Ogden and 20 miles north of Salt Lake City.

For more information about this **private practice** opportunity, send your CV to: Gordon Crawford, Professional Relations, Humana Inc., Dept. QQ-9, P.O. Box 1438, Louisville, KY 40201-1438. Or call **TOLL-FREE 1-800-626-1590.**

ORTHO-NOVUM®/// Tablets

norethindrone/ethinyl estradiol

Low incidence of androgenic side effects

Each white tablet contains 0.5 mg norethindrone and 0.035 mg ethinyl estradiol. Each light peach tablet contains 0.75 mg norethindrone and 0.035 mg ethinyl estradiol. Each peach tablet contains 1 mg norethindrone and 0.035 mg ethinyl estradiol. Each green tablet in 28-day regimen contains inert ingredients.

IMPORTANT NOTE—This information is a BRIEF SUMMARY of the complete prescribing information provided with the product and therefore should not be used as the basis for prescribing the product. This summary was prepared by deleting from the complete prescribing information certain text, tables and references. The physician should be thoroughly familiar with the complete prescribing information before prescribing the product.

INDICATIONS AND USAGE: PREVENTION OF PREGNANCY.

CONTRAINDICATIONS: Oral contraceptives should not be used in women who currently have the following conditions: 1. Thrombophlebitis or thromboembolic disorders. 2. A past history of deep vein thrombophlebitis or thromboembolic disorders. 3. Cerebral vascular or coronary artery disease. 4. Known or suspected carcinoma of the breast. 5. Carcinoma of the endometrium or other known or suspected estrogen-dependent neoplasia. 6. Undiagnosed abnormal genital bleeding. 7. Cholestatic jaundice of pregnancy or jaundice with prior pill use. 8. Hepatic adenomas or carcinomas. 9. Known or suspected pregnancy.

WARNINGS

Cigarette smoking increases the risk of serious cardiovascular side effects from oral contraceptive use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use oral contraceptives should be strongly advised not to smoke.

The use of oral contraceptives is associated with increased risks of several serious conditions including myocardial infarction, thromboembolism, stroke, hepatic neoplasia, and gallbladder disease, although the risk of serious morbidity or mortality is very small in healthy women without underlying risk factors. The risk of morbidity and mortality increases significantly in the presence of other underlying risk factors such as hypertension, hyperlipidemias, obesity and diabetes. Practitioners prescribing oral contraceptives should be familiar with the following information relating to these risks. The information contained in this brief summary is principally based on studies carried out in patients who used oral contraceptives with higher formulations of estrogens and progestogens than those in common use today. The effect of long term use of the oral contraceptives with lower formulations of both estrogens and progestogens remains to be determined. Throughout this brief summary epidemiological studies reported are of two types: retrospective or case control studies and prospective or cohort studies. Case control studies provide a measure of the relative risk of a disease, namely a *ratio* of the incidence of a disease among oral contraceptive users to that among nonusers. The relative risk does not provide information on the actual clinical occurrence of a disease. Cohort studies provide a measure of attributable risk, which is the *difference* in the incidence of disease between oral contraceptive users and nonusers. The attributable risk does provide information about the actual occurrence of a disease in the population. For further information, the reader is referred to a text on epidemiological methods. 1. THROMBOEMBOLIC DISORDERS AND OTHER VASCULAR PROBLEMS. a. Myocardial Infarction. An increased risk of myocardial infarction has been associated with oral contraceptive use. This risk is primarily in smokers or women with other underlying risk factors for coronary artery disease such as hypertension, hypercholesterolemia, morbid obesity, and diabetes. The relative risk of heart attack for current oral contraceptive users has been estimated to be two to six. The risk is very low under the age of 30. Smoking in combination with oral contraceptive use has been shown to contribute substantially to the incidence of myocardial infarctions in women in their mid-thirties or older with smoking accounting for the majority of excess cases. Mortality rates associated with circulatory disease have been shown to increase substantially in smokers, especially in those 35 years of age and older among women who use oral contraceptives. Oral contraceptives may compound the effects of well-known risk factors, such as hypertension, diabetes, hyperlipidemias, age and obesity. In particular, some progestogens are known to decrease HDL cholesterol and cause glucose intolerance, while estrogens may create a state of hyperinsulinism. Oral contraceptives have been shown to increase blood pressure among users (see section 9 in WARNINGS). Similar effects on risk factors have been associated with an increased risk of heart disease. Oral contraceptives must be used with caution in women with cardiovascular disease risk factors. b. Thromboembolism. An increased risk of thromboembolic and thrombotic disease associated with the use of oral contraceptives is well established. Case control studies have found the relative risk of users compared to non-users to be 3 for the first episode of superficial venous thrombosis, 4 to 11 for deep vein thrombosis or pulmonary embolism, and 1.5 to 6 for women with predisposing conditions for venous thromboembolic disease. Cohort studies have shown the relative risk to be somewhat lower, about 3 for new cases and about 4.5 for new cases requiring hospitalization. The risk of thromboembolic disease associated with oral contraceptives is not related to length of use and disappears after pill use is stopped. A two- to four-fold increase in relative risk of post-operative thromboembolic complications has been reported with the use of oral contraceptives. The relative risk of venous thrombosis in women who have predisposing conditions is twice that of women without such medical conditions. If feasible, oral contraceptives should be discontinued at least four weeks prior to and for two weeks after elective surgery of a type associated with an increase in risk of thromboembolism and during and following prolonged immobilization. Since the immediate postpartum period is also associated with an increased risk of thromboembolism, oral contraceptives should be started no earlier than four weeks after delivery in women who elect not to breast feed. c. Cerebrovascular diseases. Oral contraceptives have been shown to increase both the relative and attributable risks of cerebrovascular events (thrombotic and hemorrhagic strokes), although, in general, the risk is greatest among older (>35 years), hypertensive women who also smoke. Hypertension was found to be a risk factor for both users and non-users, for both types of strokes, and smoking interacted to increase the risk of stroke. In a large study, the relative risk of thrombotic strokes has been shown to range from 3 for normotensive users to 14 for users with severe hypertension. The relative risk of hemorrhagic stroke is reported to be 1.2 for non-smokers who used oral contraceptives, 2.6 for smokers who did not use oral contraceptives, 7.6 for smokers who used oral contraceptives, 1.8 for normotensive users and 25.7 for users with severe hypertension. The attributable risk is also greater in older women. d. Dose-related risk of vascular disease from oral contraceptives. A positive association has been observed between the amount of estrogen and progestogen in oral contraceptives and the risk of vascular disease. A decline in serum high density lipoproteins (HDL) has been reported with many progestational agents. A decline in serum high density lipoproteins has been associated with an increased incidence of ischemic heart disease. Because estrogens increase HDL cholesterol, the net effect of an oral contraceptive depends on a balance achieved between doses of estrogen and progestogen and the activity of the progestogen used in the contraceptive. The activity and amount of both hormones should be considered in the choice of an oral contraceptive. Minimizing exposure to estrogen and progestogen is in keeping with good principles of therapeutics. For any particular estrogen/progestogen combination, the dosage regimen prescribed should be one which contains the least amount of estrogen and progestogen that is compatible with a low failure rate and the needs of the individual patient. New acceptors of oral contraceptive agents should be started on preparations containing 0.035 mg or less of estrogen. e. Persistence of risk of vascular disease. There are two studies which have shown persistence of risk of vascular disease for ever-users of oral contraceptives. In a study in the United States, the risk of developing myocardial infarction after discontinuing oral contraceptives persists for at least 9 years for women 40-49 years who had used oral contraceptives for five or more years, but this increased risk was not demonstrated in other age groups. In another study in Great Britain, the risk of developing cerebrovascular disease persisted for at least 6 years after discontinuation of oral contraceptives, although excess risk was very small. However, both studies were performed with oral contraceptive formulations containing 50 micrograms or higher of estrogens. 2. ESTIMATES OF MORTALITY FROM CONTRACEPTIVE USE. One study gathered data from a variety of sources which have estimated the mortality rate associated with different methods of contraception at different ages. These estimates include the combined risk of death associated with contraceptive methods plus the risk attributable to pregnancy in the event of method failure. Each method of contraception has its specific benefits and risks. The study concluded that with the exception of oral contraceptive users 35 and older who smoke and 40 and older who do not smoke, mortality associated with all methods of birth control is low and below that associated with childbirth. However, smokers 35 and older and non-smokers 40 and older who use oral contraceptives have a significant increase in mortality higher than those using other methods of birth control. These facts must be weighed in conjunction with failure rates for other methods and the risk associated with subsequent pregnancy. 3. CARCINOMA OF THE REPRODUCTIVE ORGANS. Numerous epidemiological studies have been performed on the incidence of breast, endometrial, ovarian and cervical cancer in women using oral contraceptives. While there are conflicting reports most studies suggest that use of oral contraceptives is not associated with an overall increase in the risk of developing breast cancer. Some studies have reported an increased relative risk of developing breast cancer, particularly at a younger age. This increased relative risk appears to be related to duration of use. Some studies suggest that oral contraceptive use has been associated with an increase in the risk of cervical intraepithelial neoplasia in some populations of women. However, there continues to be controversy about the extent to which such findings may be due to differences in sexual behavior and other factors. 4. HEPATIC NEOPLASIA. Benign hepatic adenomas are associated with oral contraceptive use, although the incidence of benign tumors is rare in the United States. Indirect calculations have estimated the attributable risk to be in the range of 3.3 cases/100,000 for users, a risk that increases after four or more years of use especially with oral contraceptives of higher dose. Rupture of benign, hepatic adenomas may cause death through intra-abdominal hemorrhage. Studies from Britain have shown an increased risk of developing hepatocellular carcinoma in long-term (>8 years) oral contraceptive users. However, these cancers are rare in the U.S. and the attributable risk (the excess incidence) of liver cancers in oral contraceptive users approaches less than one per million users. 5. OCULAR LESIONS. There have been clinical case reports of retinal thrombosis associated with the use of oral contraceptives. Oral contraceptives should be discontinued if there is unexplained partial or complete loss of vision; onset of proptosis or diplopia, papilledema, or retinal vascular lesions. Appropriate diagnostic and therapeutic measures should be undertaken immediately. 6. ORAL CONTRACEPTIVE USE BEFORE OR DURING EARLY PREGNANCY. Extensive epidemiological studies have revealed no increased risk of birth defects in women who have used oral contraceptives prior to pregnancy. The majority of recent studies also do not indicate a teratogenic effect, particularly in so far as cardiac anomalies and limb reduction defects are concerned, when taken inadvertently during early pregnancy. The administration of oral contraceptives to induce withdrawal bleeding should not be used as a test for pregnancy. Oral contraceptives should not be used during pregnancy to treat threatened or habitual abortion. It is recommended that for any patient who has missed two consecutive periods pregnancy should be ruled out before continuing oral contraceptive use. If the patient has not adhered to the prescribed schedule, the possibility of pregnancy should be considered at the time of the first missed period. Oral contraceptive use should be discontinued until pregnancy is ruled out. 7. GALLBLADDER DISEASE. Earlier studies have reported an increased lifetime relative risk of gallbladder surgery in users of oral contraceptives and estrogens. More recent studies, however, have shown that the relative risk of developing gallbladder disease among oral contraceptive users may be minimal. The recent findings of minimal risk may be related to the use of oral contraceptive formulations containing lower hormonal doses of estrogens and progestogens. 8. CARBOHYDRATE AND LIPID METABOLIC EFFECTS. Oral contraceptives have been shown to cause a decrease in glucose tolerance in a significant percentage of users. This effect has been shown to be directly related to estrogen dose. Progestogens increase insulin secretion and create insulin resistance, this effect varying with different progestational agents. However, in the non-diabetic woman, oral contraceptives appear to have no effect on fasting blood glucose. Because of these demonstrated effects prediabetic and diabetic women in particular should be carefully monitored while taking oral contraceptives. A small proportion of women will have persistent hypertriglyceridemia while on the pill. As discussed earlier (see WARNINGS 1a and 1d), changes in serum triglycerides and lipoprotein levels have been reported in oral contraceptive users. 9. ELEVATED BLOOD PRESSURE. An increase in blood pressure has been reported in women taking oral contraceptives, and this increase is more likely in older oral contraceptive users and with extended duration of use. Data from the Royal College of General Practitioners and subsequent randomized trials have shown that the incidence of hypertension increases with increasing progestational activity. Women with a history of hypertension or hypertension-related diseases, or renal disease, should be encouraged to use another method of contraception. If women elect to use oral contraceptives, they should be monitored closely and if significant elevation of blood pressure occurs, oral contraceptives should be discontinued. For most women, elevated blood pressure will return to normal after stopping oral contraceptives, and there is no difference in the occurrence of hypertension between former and never users. 10. HEADACHE. The onset or exacerbation of migraine or development of headache with a new pattern which is recurrent, persistent or severe requires discontinuation of oral contraceptives and evaluation of the cause. 11. BLEEDING IRREGULARITIES. Breakthrough bleeding and spotting are sometimes encountered in patients on oral contraceptives, especially during the first three months of use. Non-hormonal causes should be considered and adequate diagnostic measures taken to rule out malignancy or pregnancy in the event of breakthrough bleeding as in the case of any abnormal vaginal bleeding. If pathology has been excluded, time or a change to another formulation may solve the problem. In the event of amenorrhea, pregnancy should be ruled out. Some women may encounter post-pill amenorrhea or oligomenorrhea, especially when such a condition was preexistent. 12. ECTOPIC PREGNANCY. Ectopic as well as intrauterine pregnancy may occur in contraceptive failures. **PRECAUTIONS:** 1. PHYSICAL EXAMINATION AND FOLLOW UP. A complete medical history and physical examination should be taken prior to the initiation or reinstitution of oral contraceptives and at least annually during use of oral contraceptives. These physical examinations should include special reference to blood pressure, breasts, abdomen and pelvic organs, including cervical cytology, and relevant laboratory tests. In case of undiagnosed persistent or recurrent abnormal vaginal bleeding, appropriate diagnostic measures should be conducted to rule out malignancy. Women with a strong family history of breast cancer or who have breast nodules should be monitored with particular care. 2. LIPID DISORDERS. Women who are being treated for hyperlipidemias should be followed closely if they elect to use oral contraceptives. Some progestogens may elevate LDL levels and may render the control of hyperlipidemias more difficult. 3. LIVER FUNCTION. If jaundice develops in any woman receiving such drugs, the medication should be discontinued. Steroid hormones may be poorly metabolized in patients with impaired liver function. 4. FLUID RETENTION. Oral contraceptives may cause some degree of fluid retention. They should be prescribed with caution, and only with careful monitoring, in patients with conditions which might be aggravated by fluid retention. 5. EMOTIONAL DISORDERS. Women with a history of depression should be carefully observed and the drug discontinued if depression recurs to a serious degree. 6. CONTACT LENSES. Contact lens wearers who develop visual changes or changes in lens tolerance should be assessed by an ophthalmologist. 7. DRUG INTERACTIONS. Reduced efficacy and increased incidence of breakthrough bleeding and menstrual irregularities have been associated with concomitant use of rifampin. A similar association, though less marked, has been suggested with barbiturates, phenylbutazone, phenytoin sodium, and possibly with griseofulvin, ampicillin and tetracyclines. 8. INTERACTIONS WITH LABORATORY TESTS. Certain endocrine and liver function tests and blood components may be affected by oral contraceptives: a. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3, increased norepinephrine-induced platelet aggregability. b. Increased thyroid binding globulin (TBG) leading to increased circulating total thyroid hormone, as measured by protein-bound iodine (PBI), T4 by column or by radio-immunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG, free T4 concentration is unaltered. c. Other binding proteins may be elevated in serum. d. Sex-binding globulins are increased and result in elevated levels of total circulating sex steroids and corticoids; however, free or biologically active levels remain unchanged. e. Triglycerides may be increased. f. Glucose tolerance may be decreased. g. Serum folate levels may be depressed by oral contraceptive therapy. This may be of clinical significance if a woman becomes pregnant shortly after discontinuing oral contraceptives. 9. CARCINOGENESIS. See WARNINGS section. 10. PREGNANCY. Pregnancy Category X. See CONTRAINDICATIONS and WARNINGS sections. 11. NURSING MOTHERS. Small amounts of oral contraceptive steroids have been identified in the milk of nursing mothers and a few adverse effects on the child have been reported, including jaundice and breast enlargement. In addition, oral contraceptives given in the postpartum period may interfere with lactation by decreasing the quantity and quality of breast milk. If possible, the nursing mother should be advised not to use oral contraceptives but to use other forms of contraception until she has completely weaned her child. **INFORMATION FOR THE PATIENT: See Patient Package Insert.**

ADVERSE REACTIONS: An increased risk of the following serious adverse reactions has been associated with the use of oral contraceptives (see WARNINGS section). Thrombophlebitis and venous thrombosis with or without embolism. Arterial thromboembolism. Pulmonary embolism. Myocardial infarction. Cerebral hemorrhage. Cerebral thrombosis. Hypertension. Gallbladder disease. Hepatic adenomas or benign liver tumors. The following adverse reactions have been reported in patients receiving oral contraceptives and are believed to be drug-related: Nausea. Vomiting. Gastrointestinal symptoms (such as abdominal cramps and bloating). Breakthrough bleeding. Spotting. Change in menstrual flow. Amenorrhea. Temporary infertility after discontinuation of treatment. Edema. Melasma which may persist. Breast changes: tenderness, enlargement, secretion. Change in weight (increase or decrease). Change in cervical erosion and secretion. Diminution in lactation when given immediately postpartum. Cholestatic jaundice. Migraine. Rash (allergic). Mental depression. Reduced tolerance to carbohydrates. Vaginal candidiasis. Change in corneal curvature (steepening). Intolerance to contact lenses. The following adverse reactions have been reported in users of oral contraceptives and the association has been neither confirmed nor refuted: Pre-menstrual syndrome. Cataracts. Changes in appetite. Cystitis-like syndrome. Headache. Nervousness. Dizziness. Hirsutism. Loss of scalp hair. Erythema multiforme. Erythema nodosum. Hemorrhagic eruption. Vaginitis. Porphyria. Impaired renal function. Hemolytic uremic syndrome. Acne. Changes in libido. Colitis.

OVERDOSAGE: Serious ill effects have not been reported following acute ingestion of large doses of oral contraceptives by young children. Overdosage may cause nausea and withdrawal bleeding may occur in females.

ORTHO

Outstanding Clinical Performance Reflected Inside & Outside

13 DEC 1991

GARBUTT CENTRAL LIBRARY

INSIDE

Low Metabolic Impact is reflected inside your ORTHO-NOVUM* 7/7/7 patients†: No clinically significant change in plasma glucose and insulin levels in nondiabetic women.‡[1] Mean values for total cholesterol, HDL or LDL, and blood pressure also show no significant change.§

Excellent Cycle Control is another reflection of outstanding performance with ORTHO-NOVUM 7/7/7. You can expect low discontinuation rates due to breakthrough bleeding, spotting, and amenorrhea.

OUTSIDE

Low Incidence of Androgenic Side Effects—such as acne, oily skin, or hirsutism—is a visible reflection that your patients may notice; another is no clinically significant change in mean body weight. Inside and outside, the outstanding performance of ORTHO-NOVUM 7/7/7 is also an excellent reflection on you.

Low incidence of androgenic side effects

21- and 28-day regimens

ORTHO-NOVUM 7/7/7 Tablets

TRADEMARK

norethindrone/ethinyl estradiol

---

*Trademark

†Serious as well as minor side effects have been reported with the use of oral contraceptives. The physician should remain alert to the earliest manifestations of any symptoms of serious disease and discontinue oral contraceptive therapy when appropriate.

‡Oral contraceptives have been shown to cause a decrease in glucose tolerance in a significant percentage of users. Progestogens increase insulin secretion and create insulin resistance, this effect varying with different progestational agents.

§An increase in blood pressure has been reported in women taking oral contraceptives.

Chlamydia trachomatis: Female pelvic infection

Sebastian Faro, MD, PhD

Houston, Texas

Chlamydia trachomatis is a bacterium that causes both symptomatic and asymptomatic infection. This infection has been associated with severe infections of the upper genital tract, such as salpingitis, which may be responsible for a significant number of cases of ectopic pregnancy and infertility. An unsettled question is the role of *C. trachomatis* in pregnant patients. In addition to causing cervicitis, it has been linked to chorioamnionitis, premature rupture of membranes, and premature delivery. However, chlamydial infection is an easily treatable disease. The main focus of prevention is appropriate prescreening of patients at risk. (AM J OBSTET GYNECOL 1991;164:1767-70.)

Key words: Chlamydia, salpingitis, cervicitis, azithromycin

Chlamydia trachomatis is a unique bacterium in that it is a true parasite with an extracellular and intracellular phase of its life cycle. It has a specific requirement for adenosine triphosphate, which it must obtain from the host. Its ability to colonize a host and inflict significant tissue damage is thought to be responsible for a large number of cases of infertility and ectopic pregnancies. The spectrum of disease caused by *C. trachomatis* ranges from urethritis in both men and women to Bartholin's gland abscess, cervicitis, endometritis, salpingitis, neonatal conjunctivitis, and pneumonia.

Epidemiology

The actual incidence of *C. trachomatis* infection is not known. However, the best estimates of the frequency of isolation and recovery from patients with specific diagnosis rank it as the probable leading cause of sexually transmitted disease. It is difficult actually to appreciate the involvement of this organism in female pelvic infection because the infection is often asymptomatic.

Chlamydial infection has been liked to urethritis, proctitis, epididymitis, Bartholin's gland abscess, cervicitis, endometritis, salpingitis, perihepatitis, chorioamnionitis, premature rupture of membranes, and premature delivery.[1-11] This organism has also been linked, primarily through serologic association, to infertility and ectopic pregnancy.[12, 13]

The main problem with this particular infection is not in establishing a diagnosis but in educating physicians to assess each patient for risk factors (such as having more than one sexual partner), indicating that she should be screened for possible chlamydial infection. If they suspect that their partner is not monogamous, do they use oral contraceptive pills or birth control, are they single, have they been exposed to an individual with a sexually transmitted disease, or do they have a sexually transmitted disease? Several diagnostic tests are available, such as tissue culture, direct monofluorescent antibody for the detection of antigen (Mycotrak), modification of the enzyme-linked immunosorbent assay technique (Chlamydiazyme), and a rapid test called the TestPack (Abbott Laboratories, Chicago, Ill.).

It has been estimated that 20% to 40% of all sexually active women have been exposed to *C. trachomatis* and have positive antibodies to this organism.[14] The cervical colonization or infection rate in nonpregnant women has been estimated at 3% to 5%, whereas in pregnant patients it ranges from 3% to 25%.[15, 16] The isolation rates depend on the population studied; if one is studying a population at a sexually transmitted disease clinic, the prevalence will be higher than that in a private practice setting of middle to upper income patients. For example, in Houston, Texas, among sexually active adolescents (ages 13 to 19 years old), the prevalence of *Neisseria gonorrhoea* was 7.1% and 27.4% for *C. trachomatis*, whereas among patients admitted for pelvic inflammatory disease, the prevalence of gonorrhoea

Table I. Infections caused by *C. trachomatis*

Serovar	*Infection*
A, B, Ba, C	Hyperendemic blinding trachoma
L1, L2, L3	Lymphogranuloma venereum
D, E, F, G H, I, J, K	Inclusion conjunctivitis, urethritis cervicitis, endometritis, salpingitis, epididymitis, and neonatal pneumonia

ranges from 10% to 81% and from 5% to 20% for cervical chlamydial infection.[12, 17, 18]

Infants born to women with chlamydial cervical colonization have a 60% to 70% risk of becoming infected during vaginal delivery.[19] It is estimated that approximately 25% to 50% of infants born to women with cervical colonization will develop conjunctivitis, and approximately 10% to 20% will develop pneumonia.[19-22]

Approximately 2 million cases of cervicitis and pelvic inflammatory disease are diagnosed annually.[22] About 400,000 cases are attributed to *C. trachomatis*, and these generate approximately 1 million ambulatory visits, 100,000 hospitalizations, 8050 cases of infertility, 13,900 ectopic pregnancies, and 280 deaths annually.[22] Thus the total annual cost, including indirect costs such as time lost from work, may exceed 2 billion dollars.[23, 24]

Pathophysiology

C. trachomatis is a true bacterium, because it has deoxyribonucleic acid, ribonucleic acid, and a cell wall that resembles that of gram-negative bacteria and is susceptible to antibiotics. *C. trachomatis* is an obligate intracellular parasite that has specific requirements for adenosine triphosphate and amino acids. Elementary bodies, the infectious form of the agent, attach to host cells by nonspecific forces and by binding to specific receptors.[25, 26] Endocytosis of the infectious particle occurs by a local segmental response of the host cell membrane, termed "parasite specified uptake."[27] Within the phagosome, the bacterium differentiates into the larger reticulate body form (also known as the initial form). A factor produced by the chlamydia inhibits fusion of the phagosome with cellular lysosomes, thus preventing destruction of the intracellular parasite. The specific mechanisms are unknown, but one hypothesis is that *Chlamydia* alters the protein composition of the endosomal membrane and thus prevents fusion with the lysosomes.[28] The reticulate body subsequently reproduces by binary fission. When the host cell is depleted of its adenosine triphosphate and essential amino acids, the newly formed reticulate bodies undergo a second metamorphosis and return to the elementary body form, thus completing the life cycle. The host cell is lysed and elementary bodies are released, allowing the chlamydia to infect new cells. The exact mechanism causing lysis of the host cell is unknown. However, studies have demonstrated that lysosomal enzymes are present in the cytoplasms of host cells.[29] The life cycle is completed within approximately 48 to 72 hours after entry into the host cell.

Table II. Infections caused by *C. trachomatis*

- Female
  - Bartholinitis
  - Urethritis
  - Cervicitis
  - Salpingitis
  - Preterm labor
  - Premature rupture of membranes
  - Chorioamnionitis
  - Postpartum endometritis
- Male
  - Epididymitis
  - Proctitis
  - Urethritis
- Neonate
  - Conjunctivitis
  - Pneumonia

Infection

Antigenic determinates define 15 serovars that cause three major types of infection (Table I). Infection is acquired by sexual intercourse or by contact of the mucous membrane with an infected site. The unique characteristics of *C. trachomatis* infection are its nondiscriminatory selection of the host (women, men, and children), its ability to cause asymptomatic but significant infection involving both the lower and upper genital tracts, and its potential for causing morbidity in the obstetric patient. Apparently the bacterium does not infect squamous epithelium but has a preference for columnar epithelium. The cervix is a prime target of the organism, although various other areas containing columnar epithelium are also capable of becoming infected (Table II).

Prevention

The best defense against this organism is a good offense. Condoms can be expected to reduce significantly transmission of this disease. It is imperative that the physician be alert to recognize the patient at risk. It would be neither prudent nor economically feasible to screen every patient seen for examination. If the patient is single and known to be sexually active, however, she should be screened by one of the rapid methods or culture techniques. The presumed risk factors are listed in Table III.

Individuals with a sexually transmitted disease, such as trichomonas, herpes, human papilloma virus, syphilis, and particularly, gonorrhea, should be thoroughly evaluated for *C. trachomatis*, because persons harboring one sexually transmitted disease are frequently infected with another. *N. gonorrhoea* and *C. trachomatis* are found coinfecting an individual in approximately 60% of the cases. Whenever possible, it is most appropriate to try to document the presence of chlamydial coinfection. Diagnosis is desirable to: (1) determine that treatment was effective when reexamining the patient, (2) provide specific information to the patient, (3) permit appropriate treatment of the sexual partner, and (4) determine the incidence of the infection within a given practice, which can provide information vital to the community.

Because *C. trachomatis* has been implicated in premature rupture of membranes, premature labor, chorioamnionitis, and postpartum endometritis, patients with any of these problems should be evaluated for the presence of this bacterium. However, current data have not proved conclusively a cause-and-effect relationship.[30, 31] Until that question is settled, if facilities are available to detect chlamydia, its presence or absence should be determined.

The problem with attributing postpartum endometritis to *C. trachomatis* is that no large studies have demonstrated a specific benefit from treating women with a positive culture for *C. trachomatis*. In fact several reports have documented the presence of this organism in patients with postpartum endometritis treated successfully with an antimicrobial agent that is not effective against chlamydia. The concern is that these patients are at risk for becoming infertile or will experience tubal damage and therefore will be at risk for ectopic pregnancy. Again, this has not been established by conclusive data.

On examination of the possibility of a relationship between chlamydial infection and infertility, it becomes immediately obvious that this hypothesis is based largely on immunologic data.[32, 33] Many patients who are infertile have positive serum antibodies (mainly immunoglobulin G) to *Chlamydia*. However, these data do not reveal whether these individuals experienced tubal damage because of chlamydial infection.

What is the incidence and range of chlamydial antibody among the general population? What is the incidence among persons known to have had cervical infection who subsequently become pregnant? It may be appropriate to conclude that because an individual has a positive immunoglobulin G antibody specific for *Chlamydia*, this is indeed the reason for infertility or ectopic pregnancy.

Conclusion

There is little doubt that *C. trachomatis* is one of the more frequently sexually transmitted diseases. This bacterium is commonly found to be responsible for urethritis and cervicitis. It has also been found in association with bartholinitis, endometritis, irregular uterine bleeding, and salpingitis. The frequency, however, remains to be determined. The role of this organism in obstetric patients with chorioamnionitis, premature rupture of membranes, and premature labor must still be elucidated.

Table III. Ten risk factors for acquiring *C. trachomatis*

Unmarried and sexually active
Multiple sexual partners
Use of oral contraceptive pills
Use of an intrauterine contraceptive device
History of a previous sexually transmitted disease
Known exposure with a partner having a sexually transmitted disease
Presence of a sexually transmitted disease organism, especially *N. gonorrhoeae*
Spotting after intercourse
Intermenstrual spotting whether or not the patient is taking oral contraceptive pills
Vague complaints of lower abdominal pain.

However, until the precise role of this bacterium is discovered, its presence or absence should be determined when a patient has one of these conditions. This should be done to perform a complete evaluation, determine the possible cause of the presenting condition, and administer appropriate treatment. The bacterium can be treated with a 7- to 10-day course of tetracycline, doxycycline, erythromycin, or clindamycin. Multiple-dose regimens under investigation include β-lactams, clindamycin-gentamycin combinations, and some of the fluoroquinolones. The fluoroquinolones and tetracyclines should not be used in pregnant or breast-feeding patients.

Single-dose therapy for cervicitis and urethritis caused by *C. trachomatis* is expected to eliminate the compliance problems associated with multiple-dose, multiple-day regimens. Index patients and their sexual partners could be easily treated, thereby eliminating disease recurrences resulting from noncompliance and reinfection.

The articles to follow in these symposium proceedings will present data on azithromycin, the first of the azalide class of antibiotics. The molecular characteristics of this drug result in extensive penetration of tissue and the attainment of high concentrations within cells.[34] Azithromycin's long half-life in tissue[35] is especially well matched to the prolonged life cycle of chlamydia. A single oral dose of 1 gm provides adequate levels of drug in infected tissues for a duration sufficient to eradicate infection. Azithromycin also demonstrates good in vitro activity against *N. gonorrheae* and some Enterobacteriaceae and anerobes.[36] It is excellent for the treatment of chlamydial urethritis and cervicitis.[37, 38] Azithromycin is likely also to contribute to the care of patients with pelvic inflammatory disease.

Genital chlamydial infections: Epidemiology and reproductive sequelae

Willard Cates, Jr., MD, MPH, and Judith N. Wasserheit, MD, MPH
Atlanta, Georgia, and Bethesda, Maryland

Genital chlamydial infection is increasing and is now more common than gonorrhea. A sizable percentage of chlamydial infections of the lower genital tract in women progress to endometritis and salpingitis. Tubal infertility and ectopic pregnancy are important sequelae. Failure to control chlamydial infections reflects the following four factors: (1) Many cases are mild or asymptomatic; (2) diagnostic tests are expensive and technically demanding; (3) at least 7 days of multiple-dose therapy are currently required; and (4) partner notification is not routinely performed. Thus early identification of infected persons and compliance with curative therapy are less likely than with other sexually transmitted bacterial diseases. (AM J OBSTET GYNECOL 1991;164:1771-81.)

Key words: Pelvic inflammatory disease, endometritis, salpingitis, ectopic pregnancy, nonspecific urethritis

During the past two decades, genital chlamydial infections have surpassed gonorrhea as the number one sexually transmitted bacterial infection in the United States.[1] About 4 million chlamydial infections occur each year at an estimated cost of $2.2 billion for 1990.[2] As with gonorrhea, the most important implications of genital chlamydia are the reproductive health sequelae of upper genital tract infections in women. In addition, chlamydia causes genital tract complications in men. Chlamydia apparently produces less severe symptoms than gonorrhea, but it generally seems to smolder with a minimum of patient awareness until secondary or tertiary problems arise.[3, 4]

This review describes the epidemiology and reproductive sequelae of genital chlamydial infections and will concentrate on pelvic inflammatory disease (PID) and the complications of tubal infertility and ectopic pregnancy. The article that follows will elaborate on the effects of chlamydia on pregnancy.[5]

Epidemiology

Although genital chlamydial infection is not reportable in all 50 states, national trends can be estimated through physician surveys and sentinel surveillance projects. Using the syndrome of nonspecific urethritis (NSU) in men as a proxy for chlamydial infections, incidence levels have remained high in the 1970s and 1980s. In the United States, the number of visits to private physicians' offices for the diagnosis of NSU surpassed gonorrhea in 1972 (Fig. 1). The gap has widened in recent years, with NSU now twice as common as gonococcal urethritis in men. This elevated level of NSU is more remarkable when juxtaposed against the pattern of decreasing visits for all conditions to private physicians. Thus the percentage of NSU visits has actually been increasing.

A similar picture is found in Great Britain.[6] The British use the term nongonococcal urethritis (NGU) to estimate chlamydial infections. During the 1970s and 1980s, the incidence of NGU reported to British authorities more than doubled. In England and Wales, NGU now accounts for nearly three times as many infections in men as gonorrhea.

Another estimate of the annual incidence of genital chlamydial infections was derived from a model that used a ratio of chlamydial to gonococcal infections.[7] The ratio was based on data provided by sentinel sites during the mid-1980s and on a literature review of selected prevalence studies. In 1986 chlamydia was estimated to cause more than 4 million infections in the United States—approximately 2.6 million infections occurred in women, 1.8 million in men, and 250,000 in infants. The ratio of *Chlamydia trachomatis* to *Neisseria gonorrhoeae* infections was influenced by at least five variables besides age and sex. These included race, pregnancy status, choice of contraception, the proportion of infection without symptoms, and sexual preference. Considerably higher chlamydia to gonorrhea ratios were found among whites, pregnant women, oral contraceptive users, and persons without symptoms; lower ratios were found among homosexual men.

Data from many North American metropolitan areas have also documented the predominance of chlamydial compared with gonococcal infections. For example, in Seattle, a provider-based survey of urethritis in the 1970s found markedly higher rates for NSU than for gonococcal infection.[8] The Seattle NSU to gonorrhea ratio was higher in men seen by private practitioners than in those treated in health department clinics. In Denver the incidence of NGU rose rapidly in the late 1970s and 1980s, and it became the most prevalent sexually transmitted disease in this area by the early 1980s.[9]

Chlamydia also is prevalent outside of urban areas. In a rural province in Southern Quebec (Canada), prospective surveillance of genital infections found that *C. trachomatis* was three times more frequent than *N. gonorrhoeae.*[10] In Colorado Springs, Col., similar distributions occurred.[11]

Chlamydia is apparently more difficult to transmit than gonorrhea.[12] Based on extrapolations from partner notification programs, within couples with discordant infection status, men will transmit *C. trachomatis* to their female partners 40% of the time, whereas women will transmit the infection to their male partner 32% of the time. Because these infection risks are based on the average frequency of intercourse for each couple, the transmission probability from a single coital episode is probably much lower.

During the past 5 years, a plethora of articles have been published on the prevalence and characteristics of chlamydial infections in women. These have sharpened the epidemiologic focus regarding the magnitude of infection and the consistency of risk factors. Depending on the population of women screened, the prevalence of genital chlamydia appears to range from 8% to 40%, with a typical median of 15%.[13-15] Demographic risk markers for chlamydia have been remarkably uniform—young age, unmarried status, and lower socioeconomic conditions predict higher rates. Other risk factors for cervical chlamydia in women are anatomic (ectopy), behavioral (number of sexual partners), microbiologic (concurrent gonorrhea), and hormonal (use of oral contraception).

Because of the consistency of these risk markers and factors and the financial and technical constraints on routine testing for *C. trachomatis*, attempts have been made to generate a sensitive set of predictors of chlamydial infection on the basis of nonlaboratory data from patient histories or physical examinations. For example, among patients attending a sexually transmitted disease clinic in Denver, multiple logistic regression was used to define sets of risk markers and factors that would identify patients with chlamydial infections.[16] In heterosexual men with urethral discharge, among whom 27% were infected with *C. trachomatis*, Gram's stain evidence of nongonococcal urethritis, young age, history of urethral discharge for more than a week, and absence of dysuria were factors that identified subgroups with a prevalence as high as 64%. In women, among whom the overall prevalence of infection was 17%, young age, unmarried status or a contact with gonorrhea, presence of cervical erythema or mucopus, evidence of PID, and absence of recent antibiotic use identified subgroups with a prevalence up to 61%. On the basis of these data, the investigators suggested a strategy of empiric therapy for women with four or more of these factors, laboratory testing for women with two or three of the factors, and neither testing nor

*Endometrial specimens.

treatment for the remainder. In their population this would result in antibiotic coverage of 98% of infected women while testing only 68% of clinic patients and unnecessarily treating only 9%.

Such analyses are useful primarily for local purposes to determine the actual yield of particular screening approaches. Other recent attempts to design such algorithms[17-21] have varied depending on the population to which they are applied. Thus the use of specific demographic markers, medical histories, and physical examination results to exclude persons from screening must be carefully tailored to the type of facility, characteristics of the patients, and availability of resources.

Natural history

The natural history of the chlamydial infections of the lower genital tract is uncertain. Many chlamydial infections are asymptomatic or not easily recognized on clinical grounds alone. Asymptomatic carriage in both men and women may be prolonged, further increasing the potential for transmission.[22] As many as 25% of men identified with urethral infections caused by *C. trachomatis* have no signs or symptoms of infection.[23, 24] These asymptomatic men may be an important source of infection to women unless identified through screening tests and appropriately treated.[25]

As many as 70% of women with cervical infection caused by *C. trachomatis* may be essentially without symptoms,[26] although mild symptoms of vaginal discharge, bleeding, lower abdominal pain, or dysuria may be present.[26, 27] Asymptomatic infection of the urethra and rectum caused by *C. trachomatis* can accompany infection of the cervix.[28, 29] In some women, *C. trachomatis* infection of the urethra results in symptomatic urethritis with dysuria and pyuria.[30]

Furthermore, asymptomatic chlamydial infection may lead to epidemiologic patterns that differ substantially from those of gonococcal infection. A recent study in Baltimore characterized chlamydial infections as "prevalent" infections because, in contrast to the "incident" pattern of gonococcal disease, chlamydia rates did not vary significantly by reason for clinic visit, number of sexual partners, or classification of partners as new, regular, or casual.[31]

The percentage of untreated chlamydia of the lower genital tract that ascends may be quite high. One study estimated that approximately 8% of untreated chlamydial infections progress to salpingitis[32], however, among women treated for gonorrhea with penicillin whose subsequent culture showed simultaneous cervical chlamydia, 40% had developed signs of upper genital tract infection during the 7-day follow-up interval.[33] Other studies have shown that cervical chlamydia treated only with β-lactam antibiotics tends to hibernate in the endometrium.[34] Finally, douching may play a role in producing upper genital tract infection in women with chlamydia of the lower genital tract.[35]

Oral contraceptives appear to promote acquisition of chlamydial infection of the lower genital tract.[36, 37] For example, in a recent randomized prospective study that controlled for differences in demographic factors, sexual behavior, and cervical ectopy, oral contraceptive

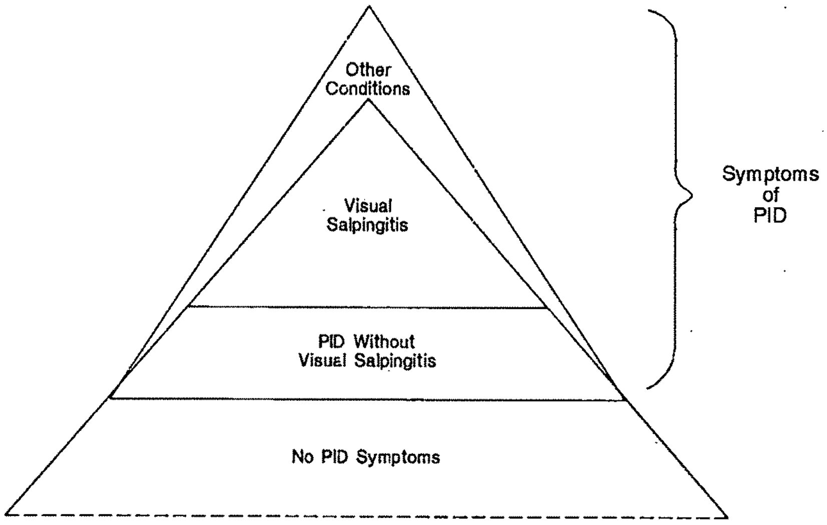

Fig. 2. Schematic representation of symptomatic and asymptomatic PID.

users developed 70% more chlamydial and gonococcal infections than women relying on intrauterine devices and tubal ligation.[38] Cervical ectopy appeared partially to explain the increased risk of chlamydial infection but did not contribute to the higher gonorrhea rates. A study in guinea pigs inoculated intravaginally supports these human data.[39] Oral contraceptive–treated guinea pigs were more likely than control animals to have prolonged chlamydial infection of the lower tract, with higher numbers of organisms and delayed appearance of local antibodies.

Whether the increase in cervical chlamydial infection associated with oral contraception affects the risk of endometrial or tubal infection is unclear.[36] In Seattle, women with cervical chlamydia who used oral contraception were less likely to develop symptoms of upper genital tract infection than those using no contraceptives.[40] Whether oral contraceptives truly reduced tubal infection or possibly suppressed inflammatory symptoms could not be resolved by this study. In addition, these data are inconsistent with results from animal models[41] and analytic studies of tubal factor infertility.[42]

Finally, chlamydial cervicitis may alter the natural history of cervical atypia. Recent preliminary data from Finland indicate that women with persistent koilocytotic atypia were almost three times as likely to have chlamydial infection (alone or together with gonorrhea) as were women in whom koilocytosis resolved. Although the association did not reach statistical significance, it is consistent with other data linking chlamydial infections to an increased risk of cervical neoplasia.[43]

Sequelae: PID

Both microbiologic and serologic measures have established *C. trachomatis* as an important sexually transmitted organism leading to upper genital tract infection.[44] However, the rate at which chlamydial and gonococcal organisms have been recovered in patients with symptoms of PID varies widely. This variation is probably from differences among the populations studied, in the time period during which the investigations took place, in methods used to recover the organisms, and in the severity of infection.

In both Europe and North America, more recent investigations[45-67] have generally found a higher proportion of *C. trachomatis* than *N. gonorrhoeae* in women with symptoms of PID (Table I). In Scandinavia, between one quarter and one half of PID was associated with culture, serologic evidence, or both of *C. trachomatis* infection. Chlamydia has also been isolated in as many as 51% of some North American populations.[59]

In nearly all studies of women with symptoms of PID in whom abdominal cultures were taken, chlamydia was isolated at a lower rate from tubal than from cervical specimens (Table I). This is not unexpected, since extraluminal swabs may not be as efficient in obtaining organisms as endocervical techniques and smaller numbers of organisms may reach the tubes than reach the cervix. Moreover, local neutralizing antibodies may limit culture sensitivity at the intratubal level. Detection of chlamydia antibodies, indicative of either present or past infection, was usually more frequent than isolation of organisms from the cervix or tubes.

Based on our evolving knowledge of PID, asymptomatic ("silent") or "atypical" syndromes have assumed a greater importance (Fig. 2). Because of its smoldering nature, chlamydial infection plays a key role in this problem. Chronic, subacute, or latent endometrial and tubal infection is probably present in a large number of women, but a consensus definition of these clinically subtle infections is lacking.[68] Moreover, the magnitude of the problem is unknown. Endometritis has been

found in 40% of women with cervicitis who had no symptoms of PID at the time of referral.[69] Conversely, in three of nine women with symptoms of PID but normal external tubal serosa at laparoscopy, endometrial biopsy specimens revealed plasma cell endometritis; moreover, several weeks later the endometrial infection eventually led to salpingitis.[70]

Thus PID, which both causes symptoms and also produces visually detectable salpingitis, probably accounts for less than half of the total cases. After a decade of using the term "acute salpingitis" to provide specific diagnoses, clinical evidence now appears to favor a more sensitive definition of PID. Not only does the upper genital tract infection affect more than just the fallopian tubes but also the tubes themselves can be involved without visual evidence of salpingitis. Future efforts to identify women with smoldering upper genital tract infection will have to rely on atypical symptoms (e.g., abnormal or increased bleeding) or biochemical markers (e.g., tumor-associated trypsin inhibitor and C-reactive protein).

Sequelae: Tubal infertility

Acute salpingitis, whether related to *C. trachomatis, N. gonorrhoeae,* both organisms, or neither, is causally related to tubal infertility.[71] However, silent salpingitis accounts for a sizable proportion of tubal infertility, probably the majority. Nearly all investigations have found that more than half of the women with documented tubal occlusion report no history of previous PID despite serologic evidence of past chlamydial infection.[72, 73] Moreover, morphologic and physical analyses of tubal epithelium from women with distal tubal obstruction found extensive ultrastructural damage, even in those without knowledge of previous PID.[74]

A large number of investigations from 14 countries (Table II) have examined the relationship between serologic evidence of past chlamydial infection and tubal infertility.[74-94] Despite wide variations in design, these studies have uniformly found a significant association between tubal occlusion and serologic evidence of prior chlamydial infection. In addition, five of the six additional studies,[95-100] which included both chlamydial and gonococcal antibodies (Table III), implied independent etiologic associations between the infections and tubal infertility. Only one study in Bristol, England, found no relation to previous gonococcal infection.

Cohort studies verify the link between sexually transmitted diseases, PID, and tubal infertility. In Lund, Sweden, among women with symptoms of laparoscopically verified salpingitis, similar levels of tubal occlusion occurred regardless of whether gonorrhea, chlamydia, both organisms, or neither was isolated from the cervix.[101, 102] In Winnipeg further evidence of PID sequelae was confirmed in a study of 50 women with laparoscopically verified acute salpingitis.[66] Of the 50 women, 23 attempted to become pregnant and had a subsequent evaluation to determine their fertility status. Seven of 13 women with nongonococcal infection had an adverse reproductive outcome compared

EP, Ectopic pregnancy; *UD/TL*, intrauterine device/tubal ligation.

with none of 10 women with gonococcal infection ($p = 0.007$). Two factors were associated with adverse reproductive outcome: four of the seven infertile women had initial tubal abscesses, and three had evidence of *C. trachomatis.*

Chlamydia apparently causes more severe subclinical tubal inflammation and, ultimately, tubal damage than other agents despite its more benign-appearing symptoms and signs.[103-105] Colonization of the fallopian tube by *C. trachomatis* has been found in infertile women without symptoms in the absence of laparoscopic signs of active pelvic infection.[106] The severity of tubal damage despite mild clinical symptoms is probably because chlamydial salpingitis is more chronic than salpingitis caused by other organisms. This hypothesis is supported by the low prevalence of immunoglobulin M antibody to chlamydia among women with acute salpingitis.[18]

The mechanism that accounts for tubal occlusion after chlamydial infection is unknown. An indirect and long-term process may be responsible. Animal studies have demonstrated that single chlamydial infections have been self-limiting with little residual damage; however, repeated chlamydial infection eventually produces tubal occlusion and infertility.[107] Serial inoculations of chlamydia directly into the fallopian tube of pig-tailed monkeys result in intratubal adhesions and distal tubal obstruction.[108] Similar histopathologic findings occurred after tubal challenge that followed repeated chlamydial cervical infection.[109] Whether this represents immune-mediated tubal destruction or exacerbation of chronic, active chlamydial infection is not clear.[110] γ-Interferon may also be involved with chlamydial mechanisms of pathogenesis.[111] Untreated chlamydial salpingitis may show symptoms of resolution in the face of progressive damage. Moreover, in mice, treatment with tetracycline had to be started early in the course of tubal infection to have any influence in reducing infertility.[112]

Sequelae: Ectopic pregnancy

Ectopic pregnancy is also associated with prior chlamydial PID. Several case-control studies[113-120] have demonstrated an association between chlamydial infection and ectopic pregnancy, with adjusted relative risks ranging between 2.4 and 7.9 (Table IV). The cohort study of salpingitis in Lund, Sweden, provides the strongest etiologic evidence of an association between PID and ectopic pregnancy.[121] Of 544 women with acute salpingitis proved at laparoscopy, 7% of the first pregnancies in these women were ectopic. Among control women with no acute salpingitis, less than 1% of the subsequent pregnancies were ectopic.[102]

Case-control studies of ectopic pregnancy that incorporated serologic tests for chlamydial infection have also shown strong associations (Table IV). The relationship between chlamydial serologic findings and ectopic pregnancy was particularly high among women who did not use intrauterine devices at conception. In England, chlamydial antibodies were more than two times more frequent than gonococcal antibodies among women with ectopic pregnancy.[116] However, evidence of previous infection with both these organisms was significantly higher in women with ectopic pregnancy than in the those with intrauterine pregnancies. In addition, an independent association between *C. trachomatis* and ectopic pregnancy was found in a recent study from the United States that controlled for douching as a risk behavior.[119]

Moreover, "silent" salpingitis may also be related to ectopic pregnancy.[122] Among 27 women who had an ectopic pregnancy after attending an infertility clinic, previous laparoscopy had indicated "normal" tubal morphologic findings in 12 (44%). Eight fallopian tubes were available from these 12 women for histologic examination after the ectopic pregnancy. All eight had evidence of ongoing, low-grade salpingitis. These findings suggest that laparoscopy cannot exclude smoldering intraluminal tubal disease in some women with normal serosal findings.

Conclusion

Genital chlamydial infections remain an important cause of preventable reproductive morbidity in the United States. During the past two decades, we have learned much about the factors related to infection with *C. trachomatis* and the insidious sequelae that eventually result. Failure to control chlamydial infections is a reflection of the following four factors: (1) Both symptoms and signs of chlamydial infection are often either extremely mild or totally absent; (2) tests for *C. trachomatis* are expensive and technically demanding; (3) at least 7 days of multiple-dose therapy are necessary to eradicate the organism; and (4) partner notification is not routinely performed for patients with chlamydial syndromes. Together these factors mean that early identification of infected individuals and compliance with curative therapy are less likely to occur with chlamydial infection than with other bacterial sexually transmitted diseases. However, when aggressive programs to control chlamydia are undertaken by communities, a measurable impact on lowering these smoldering genital infections can result.[123, 124]

Chlamydia trachomatis infection during pregnancy

James A. McGregor, MD, CM, and Janice I. French, CNM, MS
Denver, Colorado

Although transmission of *Chlamydia trachomatis* to infants during vaginal birth can result in conjunctivitis and pneumonitis, there is uncertainty about other adverse effects of chlamydial infection during pregnancy. There is some evidence that it may contribute to adverse complications such as premature rupture of membranes, preterm labor and birth, low birth weight, and still birth. Infection with *C. trachomatis* is also implicated in postabortal, postcesarean section, and postpartum maternal infections. Treatment of chlamydial infection during pregnancy has proved beneficial in the prevention of neonatal morbidity and is now recommended by the Centers for Disease Control. (Am J Obstet Gynecol 1991;164:1782-9.)

Key words: *C. trachomatis*, premature rupture of membranes, conjunctivitis, pneumonitis, neonatal morbidity

Chlamydia trachomatis is a well-established cause of pelvic inflammatory disease (endometritis or salpingitis) in women, urethritis and epididymitis in men, and conjunctivitis and pneumonitis in newborn infants. In the United States, an estimated 155,000 infants are exposed to the organism during the birth process each year, and more than 100,000 become infected.[1]

Interest in the possible roles of chlamydia in perinatal infection began more than 80 years ago with von Halberstaedter and Prowazek's[2] description of neonatal conjunctivitis associated with parental cervicitis, urethritis, and the microscopic presence of inclusion bodies. They first observed these organisms in conjunctival cells from patients with trachoma and named them "chlamydozoa," from the Greek word for "cloak." Even today uncertainty continues with regard to the following: (1) the role of chlamydia in maternal and neonatal infectious morbidity; (2) the extent to which chlamydia infection during pregnancy contributes to premature rupture of membranes (PROM), preterm birth, low birth weight, and puerperal infection; and (3) cost-effective approaches to the evaluation and treatment of pregnant women potentially infected with chlamydia.

We will briefly review the present understanding of this common sexually transmitted infection during pregnancy and offer recommendations for management. More comprehensive reviews of chlamydial infection during pregnancy are available.[3, 4]

Epidemiology

Epidemiologic aspects of chlamydial infection of the reproductive tract have been reviewed.[3, 5, 6] The prevalence of both symptomatic and asymptomatic genital chlamydial infection varies from under 2% among private obstetric patients to well over 20% among groups of younger women receiving care at public clinics. Epidemiologic factors associated with increased risk of infection include age less than 24 years, nonwhite race, use of oral contraceptives, and nonuse of barrier forms of contraception.[7-10]

Infection occurs most frequently among women aged 15 to 21 years and declines markedly with advancing age; in contrast, the prevalence of chlamydial antibody positivity increases with age until approximately age 30 years, when it plateaus in women at up to 50%.[11] Epidemiologic factors are useful to predict rates of infection among some groups of pregnant women but not to determine the presence of infection among persons.[12]

With rare exception, transmission from the infected mother to her newborn infant occurs during vaginal delivery through an infected cervix, and transmission rates range from 23% to 70%.[6, 13] Higher rates of vertical transmission are microbiologically documented if exposed infants have serial cultures done over several months.[14] Several instances of infection before birth or among infants born by cesarean section have also been reported.[15-17] Frommel et al.[8] noted an association with breast-feeding and suggested that intimate handling of newborn infants may play a role in transmission. Nevertheless, it appears that the vast majority of neonatal chlamydial infections occur during birth and thus are amenable to identification and preemptive treatment during pregnancy.

Microbiology and pathophysiology

C. trachomatis (genital serovars D to K) are small obligate, intracellular, gram-negative bacteria. Chlamydiae develop intracellularly within cytoplasmic vacuoles. Their unique developmental cycle includes production of precursor initial and reticulate bodies and release of infectious elementary bodies. Release of the

elementary bodies occurs by cell rupture, with subsequent cell death accounting for direct tissue and organ damage. Such intracellular organisms are relatively protected from humorally mediated host defenses, which may account for the typically low antibody levels in uncomplicated infection and the prolonged persistence of untreated infection. Despite difficulties culturing *C. trachomatis*, elementary bodies are not fragile and may be infectious for several days.[5] Elementary bodies appear to induce phagocytosis by "nonprofessional" phagocytic cells, including squamocolumnar epithelia found in conjunctiva, the respiratory tract, and the mucous membranes of the genitourinary tract.

Approximately 30% to 40% of endocervical infections spread to the contiguous endometrium.[18] Infection and destruction of cervical, endometrial, and fallopian tube-lining cells may impair fertility, increase the risk of ectopic pregnancy, or damage a developing pregnancy. It is speculated that pregnancy loss, inadequate fetal development, bleeding, preterm labor, or PROM may result from persistent upper reproductive tract infection by *C. trachomatis*.

Other effects of chlamydial infection may also interfere with subsequent pregnancy. It is possible that presentation of host chlamydial epitopes on infected cell surfaces may induce altered immunologic responses. In an animal model of salpingitis, Patton et al.[19] demonstrated a florid inflammatory response to reinoculation of chlamydia. It is thought that an autoimmune reaction to chlamydial infection is the most common cause of Reiter syndrome or reactive arthritis among patients with permissive major histocompatibility (MHC) gene allotypes.[11]

Similarly, acute or persistent chlamydial infection of endometrial or decidual cells or fetal trophoblast cells may fundamentally alter maternal-fetal tolerance mechanisms that are integral to successful pregnancy. MHC molecules are normally suppressed in cells adjacent to the maternal-fetal interface. In vitro infection of decidual cells with *C. trachomatis*, however, sharply increases cell surface production of MHC molecules essential for immunologic recognition.

Infection with chlamydia also increases production and release of tumor necrosis factor, interferons, and interleukin-2 by infected cells.[20] Increased local tissue concentrations of these cytokines may enhance immunologic surveillance and decrease cell-mediated tolerance at maternal-fetus interfaces. Moreover, when inflammatory cells such as monocytes are exposed to *C. trachomatis*, they release relatively large amounts of interleukin-1. This cytokine may directly damage infected cells and is well known to amplify the response to other inflammatory mediators.

Endocrinologic changes associated with pregnancy may increase the virulence of both symptomatic and asymptomatic chlamydial infection. With the use of a

Rank et al.[21] demonstrated that treatment with estradiol resulted in florid endometritis, salpingitis, and cystitis. In contrast, infection in control animals was limited to the vagina and the cervix. Moreover, direct *C. trachomatis* infection may occur more commonly in trophoblastic tissue and the conceptus than is generally recognized. Harrison and Riggin[22] demonstrated that preparations of human amnion cells were as easily infected with chlamydia as were 5-iodo-2-deoxyuridine–treated cells used in routine culture. Neeper et al.[23] also demonstrated robust chlamydial infection of human amnion cells in fetal membrane explants. The failure of *C. trachomatis* to cause frequent intraamniotic infection may be explained by an as yet unidentified antichlamydial factor present in human amniotic fluid.[24] The possible importance of as yet unstudied aspects of chlamydial host susceptibility and strain virulence is suggested by several well-described instances of maternal sepsis caused by *Chlamydia psittaci* with intrauterine infection and fetal death.[4]

Neonatal transmission

Vertical transmission of *C. trachomatis* during vaginal birth typically occurs in 50% to 60% and as many as 70% of infants born to infected women.[12, 13, 25, 26] Prospective serial microbiologic surveillance has shown that colonization or infection may take weeks to months to become detectable[12] and that multiple sites (conjunctiva, nasopharynx, rectum, and vagina) may become infected or colonized.[12, 25, 26] Not all exposed or infected infants develop recognizable findings or symptoms; risks of clinically recognized conjunctivitis range from 18% to 50%.[25-29] Prospective examination of lacrimal fluid for inflammatory changes or microimmunofluorescent antichlamydial antibody testing may be a more sensitive measure of infection than cultures.[25] Recent studies show that 1% silver nitrate ($AgNO_3$) can be as effective as erythromycin or tetracycline ophthalmic ointments in prophylaxis of chlamydial conjunctivitis.[28] This suggests that prior estimates of vertical transmission that used newborn infants treated with silver nitrate as control subjects gave falsely low results.

Newborn chlamydial conjunctivitis occurs several weeks post partum and frequently runs a mild course ("glue eye"). However, severe exudative ophthalmitis can occur. On rare occasions, conjunctival scarring may be noted. It is commonly hypothesized that after chlamydiae have infected the conjunctiva, elementary bodies pass through the lacrimal duct to the nasopharynx and subsequently to the lower respiratory tract. Nasopharyngeal inoculation also occurs primarily at the time of birth; Hammerschlag et al.[27] found that the nasopharynx was the most common site of recovery after birth. Alexander and Harrison[29] noted that 15% to 20% of exposed infants developed nasopharyngeal infection or colonization and that a full one third de-

dence of chlamydial pneumonia was between 10% and 16%.[27, 29] Although most other investigators show similar results, prospective studies by Heggie et al.[13] do not show any increase in respiratory illness among infants exposed to chlamydia at birth.

Chlamydial pneumonitis is usually recognized between 6 weeks and 6 months of life.[30] Although chlamydial pneumonia is usually not progressive, affected patients frequently require hospitalization and may be predisposed to prolonged respiratory disease with impaired lung function. Chlamydial pneumonitis is clinically indistinguishable from pneumonitis caused by other pathogens infecting the newborn infant.[8, 30] As many as two thirds of cases of chlamydial pneumonitis may be associated with concomitant cytomegalovirus, *Ureaplasma urealyticum*, or *Pneumocystis carinii* infection.[8, 30] Both cytomegalovirus and genital mycoplasmas may also be transmitted to the fetus around the time of birth.

Approximately one half of the cases of pneumonitis occur in the absence of clinically recognized conjunctivitis.[29] The absence of prodromal conjunctivitis belies the assumption that chlamydial pneumonitis can be prevented by systemic treatment of newborns with conjunctivitis.

C. trachomatis is also implicated but not yet proved as a cause of otitis media, bronchiolitis, vulvitis, proctitis, and gastroenteritis in infants. Although neonatal conjunctivitis is usually not severe, topical treatment is often ineffective. Oral erythromycin is used in the newborn infant to treat chlamydial conjunctivitis effectively, as well as to reduce or eliminate chlamydial infection at other sites.

Postabortal and postpartum maternal infection

Women with cervical infection from *C. trachomatis* at the time of elective abortion are at increased risk for postabortal endometritis. In prospective European studies, 22% to 38% of chlamydia-infected women develop postabortal pelvic infection compared with 2% to 10% of those without chlamydia.[31, 32] Chlamydial postabortal endometritis tends to occur approximately 3 to 10 days later than nonchlamydial endometritis. It is not known whether endometritis, which is found in 30% to 40% of nonpregnant women with cervical infection,[18] affects risks of postabortal infection or whether chlamydia-infected women aborting spontaneously carry similar risks.

Optimally, women should be screened and treated for both *C. trachomatis* and *Neisseria gonorrhoeae* before termination of pregnancy. Alternatively, tests for *C. trachomatis* could be done immediately before the procedure, with treatment initiated promptly after the microbiologic diagnosis. Full-treatment doses of doxycycline or tetracycline should be given. Short "prophylactic" courses of tetracycline or erythromycin are ineffective for eradication of chlamydial infection and may not reliably prevent postabortal morbidity.

The roles for *C. trachomatis* in endometrial infection post partum and after cesarean section remain less well established. In one well-studied case, Cytryn et al.[33] cultured *C. trachomatis* from the peritoneal fluid of a 17-year-old woman with a severe infection after cesarean section. In a prospective study Wager noted delayed (>48 hours to 6 weeks) infectious morbidity in 10 (34%) of 29 women with chlamydial infection delivering vaginally compared with 23 (8%) of 300 uninfected women.[34] In marked contrast, other studies fail to link cervical chlamydial infection with puerperal infection. Prospective studies by Harrison et al.[35, 36] and others[37] show no increase in postpartum infection attributable to *C. trachomatis*. In a case-controlled comparison between women with and without infection after cesarean section, Blanco et al.[38] found no increased carriage of chlamydia among infected mothers. A more recent study by Berenson et al.[39] noted a 20% rate of chlamydial carriage or infection among adolescent women with infectious morbidity after cesarean section, but this was not different from the control teenagers. Although the preponderance of findings did not show that chlamydia was a common cause of postpartum infection, clinicians should be aware that such infections occur occasionally. As in the case described by Cytryn et al.[33] clinical recovery may not occur until specific treatment for *C. trachomatis* is administered. If chlamydiae are recovered from postpartum women, the newborn infant, as well as mother's sexual contacts, should be evaluated and treated.

C. trachomatis infection and pregnancy outcome

Various studies have examined the possible roles of maternal *C. trachomatis* infection in adverse pregnancy outcomes. Suggested complications include PROM, preterm labor and birth, low birth weight (<2500 gm), intrauterine growth retardation, and stillbirth, as well as intrapartum and postpartum maternal and neonatal infectious morbidity.

In a 1982 study Martin et al.[40] prospectively evaluated 268 pregnant women and found that 6.7% had findings of positive *C. trachomatis* infection before 19 weeks' gestation. There was a 33% perinatal mortality rate (three fetal and three neonatal deaths) among infected women, but only one neonatal death occurred among uninfected women. Five (28%) of the 18 infected mothers delivered before 37 weeks' gestation compared with 15 (6%) of the 238 uninfected mothers. This investigation led to calls for studies in which other possible associated factors would be analyzed. Subsequently, in a prospective study of 534 pregnant women, Gravett et al.[41] found that cervical infection with *C. trachomatis* was independently associated with PROM, preterm labor, and low birth weight (odds ratio [OR] 2.7; confi-

dence interval 95% [CI] 1.3 to 5.7; $p = 0.01$).[41] In a case study comparing preterm and term deliveries, Martius et al.[42] found an increased association between chlamydia and preterm birth (OR 5.4; 95% CI 1.3 to 23.4; $p = 0.02$). This finding was unchanged after adjustment for the presence of bacterial vaginosis, lactobacillus, or PROM, which suggests an independent effect of *C. trachomatis*. In the largest prospective study of chlamydial cervical infection during pregnancy that controlled for the presence of *Mycoplasma hominis* and other possible risk factors, Polk et al.[43] found that *C. trachomatis* was significantly associated with preterm birth (OR 1.6; 90% CI 1.01 to 2.5) and intrauterine growth retardation (OR 2.4; 90% CI 1.32 to 4.18). The reason for using 90% rather than 95% CI was not explained. On the other hand, a large number of generally smaller prospective studies fail to show an overall association between maternal chlamydial infection and a poor reproductive outcome.[13, 35-37, 44-50]

Insight into these conflicting results is furnished by several prospective studies demonstrating that PROM, preterm birth, and low birth weight were associated with chlamydial infection only among women with an immunoglobulin M antichlamydial antibody response during pregnancy (Table I). Such findings suggest that women with either recent or more extensive and invasive chlamydial infection, possibly involving the upper reproductive tract, are at increased risk.[35, 36, 44] Harrison et al.[35] noted that a full 24% of chlamydia-positive women (8% of the total) were immunoglobulin M positive.

Additional insight into the pathophysiology of chlamydial infection during pregnancy comes from a prospective study by Hardy et al.,[47] which demonstrated an increase in preterm birth and low birth weight only in the presence of coinfection with *Trichomonas vaginalis*. Possible additive or synergistic effects of cervical vaginal microorganisms or bacterial vaginosis have been demonstrated by others.[37]

Further intriguing findings regarding the role of chlamydia in complications of pregnancy come from several prospective, controlled studies of the treatment of chlamydial infection during pregnancy. Ryan et al.[51] obtained cultures from 11,544 women to determine the presence of *C. trachomatis* at the initial prenatal visit. Twenty-one percent were documented to be infected; approximately one half of these women received treatment over several years. Women who remained untreated (1110) had a significant increase in occurrences of PROM, low birth weight, and decreased perinatal survival compared with either treated women (1323) or women with negative cultures (9111).

In a similar but smaller comparative study, Cohen et al.[52] analyzed the pregnancy outcomes of 244 women successfully treated with erythromycin, 79 chlamydia-positive women who failed to comply with or respond to treatment, and 244 chlamydia-free women. Fre-

Table II. Summary of Centers for Disease Control recommendations for screening and treatment of maternal *C. trachomatis* infection in pregnant women

A.	Who? Pregnant women should undergo diagnostic tests* for *C. trachomatis* *N. gonorrhoeae* Syphilis
B.	When? Initial visit and again in third trimester if judged at increased risk; i.e., <25 yr of age, history of sexually transmitted disease, new (<3 mo) sexual partner or multiple partners
C.	Recommended regimens?†‡ Oral erythromycin base, 500 mg four times daily, for 7 days If poorly tolerated: Oral erythromycin base, 250 mg four times daily, for 14 days or Oral amoxicillin, 500 mg three times daily, for 7 days
D.	Partner: Evaluate and treat if contact within 30 days, if tests unavailable, treat
E.	Tests of cure (by culture) are not recommended unless there is question of patient compliance

†Poor tolerance is treated with supportive care or use alternative regimen.

‡Enteric-coated or sustained-release preparations of erythromycin are also effective but more costly.

quencies of preterm delivery (3% vs 14%, $p = 0.0002$), ruptured membranes (7% vs 20%), preterm labor (4% vs 24%), and small for gestational age newborns (13% vs 25%) were significantly lower among successfully treated patients than in patients considered treatment failures. Successfully treated women had outcomes similar to those of uninfected control mothers. Other complications, including stillbirth and postpartum endometritis, were similar among all three groups.

In the only double-blind, randomized, placebo-controlled trial of the treatment of chlamydia during pregnancy,[53] 125 infected pregnant women enrolled before 24 weeks' gestation were treated with either erythromycin, clindamycin, or placebo. No differences in effectiveness between clindamycin or erythromycin were noted. Although patients with preterm PROM were more likely to have been infected with *C. trachomatis* (or trichomoniasis), eradication of *C. trachomatis* before the third trimester failed to reduce significantly the occurrences of PROM, preterm birth, low birth weight, or maternal infectious morbidity in this small but well-controlled study.

Such inconsistent findings are not necessarily unexpected when one considers variations in study size, appropriateness of controls, prevalence of infection, type of microbiologic diagnosis, serologic assessment, and attempts to control for confounding factors. Several large-scale, controlled, prospective studies of erythromycin treatment during pregnancy are in progress and should furnish further information on chlamydia-associated pregnancy morbidity as well as the effects of treatment. Furthermore, metaanalysis may be used to aggregate the findings of comparable studies and may reveal new information regarding the roles of chlamydial infection of the reproductive tract and various populations.

Diagnosis

The methodology of both culture and nonculture microbiologic tests for *C. trachomatis* is not altered during pregnancy.[53, 54] Careful specimen collection, handling, and processing are important for optimal diagnosis. In both pregnant and nonpregnant women, chlamydial cultures are 100% specific and approximately 80% to 90% sensitive.[53, 54]

In a population of pregnant women with a relatively high prevalence of infection (21.5%), sensitivities and specificities for a direct fluorescent antibody test were 98% and 95%, respectively.[55] Similar results of 96% and 93%, respectively, were also noted for an enzyme immunoassay test.[54] In groups of women with lower prevalences of chlamydial infection, culture techniques may be considerably more accurate.

Alternative methods such as deoxyribonucleic acid hybridization and polymerase chain reaction are being developed.[56, 57] Anecdotal information suggests that identification of presumed chlamydial infection by examination of cervical mucin for white blood cells or discoloration is less accurate in pregnant than in nonpregnant women.

Ongoing advances in culture, antigen detection, and molecular biologic techniques will permit less costly but equally accurate diagnosis of chlamydial infection.

Present recommendations for screening and treatment

Although the effects of antichlamydial therapy on pregnancy outcomes, such as preterm birth, PROM, and postpartum endometritis, remain uncertain, the benefits of identifying and treating infection during pregnancy to prevent neonatal infection and morbidity are increasingly clear. Postpartum topically applied chemoprophylaxis should be retained, although it provides incomplete protection. Topical application of erythromycin or tetracycline to prevent conjunctivitis has not prevented pneumonia and subsequent respiratory disease, because conjunctival prophylaxis does not eliminate colonization of the respiratory tract. Recent studies have confirmed Bell's original suggestions that topical antibiotic prophylaxis is no more effective than the less expensive 1% silver nitrate fluid prophylaxis.[28]

To prevent neonatal morbidity, identification and eradication of maternal chlamydial infection during pregnancy are required. A large prospective, nonrandomized study by Schachter et al.[58] and smaller studies by FitzSimmons et al.,[46] Black-Payne et al.,[59] and McMillan et al.[60] demonstrate that the diagnosis of chlamydia by culture or antigen-based techniques permits effective treatment with erythromycin and successful prevention of chlamydia-associated morbidity in newborn infants.

Schachter et al.[58] offered treatment with oral erythromycin ethylsuccinate, 400 mg four times a day, for 7 days at 36 weeks' gestation to 184 pregnant women with cervical chlamydial infection. Thirty-two women refused treatment and served as control subjects. Of the 152 women who took the medication, 10 complained of gastrointestinal disturbances, and erythromycin had to be discontinued in 5 women. Of those who completed the protocol, 92% had negative findings of chlamydia. Chlamydial infection or colonization occurred in only 7% of the newborn infants of treated mothers compared with 50% of infants born of untreated women.

FitzSimmons et al.[46] followed 33 women infected with cervical chlamydia during the first half of pregnancy and started treatment at 36 weeks' gestation. None of the infants of the 18 women who received adequate treatment with erythromycin had infection or chlamydial-linked morbidity. Conversely, two of the three newborn infants of untreated women had positive findings of chlamydia. Treatment at 36 weeks does not allow for prophylaxis for women delivering preterm or for women who were away during the course of care.

Black-Payne et al.[59] used an enzymatic immunoassay test for the diagnosis of chlamydial cervicitis between weeks 28 and 32 of pregnancy and provided treatment with oral erythromycin. Although 16% of their patients noted side effects, 92% completed therapy, with apparent elimination of excess chlamydial-associated morbidity. The double-blind, randomized trial of Alger and Lovchik[53] showed that oral erythromycin or clindamycin was as well tolerated as placebo.

Although these studies did not demonstrate high rates of intolerance to erythromycin during pregnancy, anecdotal reports from several institutions and our observations[49] suggest that a substantial number of pregnant women do not complete erythromycin therapy because of adverse gastrointestinal effects. In such cases, reduced doses of erythromycin or use of agents such as clindamycin and amoxicillin may be better tolerated.[61, 62] Both clindamycin and amoxicillin appear effective and may offer real advantages for the treatment of chlamydial infection during pregnancy.[61-63]

The Centers for Disease Control has recently issued new recommendations regarding screening and treatment of *C. trachomatis* during pregnancy (Table II).[62] At this time, treatment late in pregnancy is recommended to prevent perinatal infection caused by maternal reinfection or relapse. Alternatively, screening and treatment may be completed early in pregnancy, with reculture and treatment near term in selected women. In either instance sexual partners should be sought, evaluated, and treated for chlamydia. Similarly, both parents of chlamydia-infected infants should be evaluated and treated.

New treatments for *Chlamydia trachomatis*

Robert B. Jones, MD, PhD
Indianapolis, Indiana

Standard regimens of tetracycline, doxycycline, or erythromycin, if complied with, appear to be effective against *Chlamydia trachomatis* infections under most circumstances. However, the organism may sometimes persist despite what would seem to be adequate therapy. How often this occurs, to what extent noncompliance is the issue, and the role antibiotic resistance plays remain to be determined. Among newer antibiotics, azithromycin appears to be effective in the treatment of uncomplicated urogenital *C. trachomatis* infections. Single-dose therapy with azithromycin may be especially useful in overcoming compliance problems associated with the treatment of sexually transmitted disease. (Am J Obstet Gynecol 1991;164:1789-93.)

Key words: *C. trachomatis*, recurrent infection, antibiotics, azithromycin

Chlamydia trachomatis infections of the genital tract are prevalent among young, sexually active persons. They are associated with considerable morbidity, including infertility, ectopic pregnancy, infant pneumonia, and conjunctivitis.[1,2] Efforts at controlling transmission and preventing complications have focused on the identification of infected persons and treatment with effective antibiotics. Selection of the antibiotic has been based primarily on demonstrated efficacy in clinical trials and on cost.[3,4]

The treatment presently recommended for uncomplicated genital tract infection with *C. trachomatis* is doxycycline, 100 mg orally twice a day for 7 days, or tetracycline, 500 mg orally 4 times a day for 7 days.[5] The essential therapeutic equivalency of tetracycline, doxycycline, and minocycline has been established in several clinical trials.[4] Doxycycline has become the preferred agent, because less frequent dosing is required.[5] Minocycline has been used less often because of vestibular side effecs, particularly at higher doses.

Of interest has been the observations that clindamycin in combination with an aminoglycoside has been effective in eradicating *C. trachomatis* in women with salpingitis,[6] whereas clindamycin alone was ineffective in treating men with chlamydial urethritis.[7] A possible explanation may lie in the recent demonstration of in vitro synergy of clindamycin and gentamicin or tobramycin against *C. trachomatis* despite the fact that the aminoglycosides are inactive when used alone.[8]

Recurrent or persistent infections

Although the present treatment regimens appear effective in most patients who are compliant, there has been a failure rate of approximately 5% in most studies in which a test-of-cure culture is obtained 4 to 7 days

Table I. Time to recurrence of *C. trachomatis* infection in adolescent girls

Mo after initial infection	*Recurrence rate*	
	No. positive/No. tested	*%*
0-3	4/34*	12
3-6	20/79	25
6-9	13/34	38
9-12	13/34	38
12-15	4/20	20
15-18	7/13	54
18-21	4/7	57
21-24	3/5	60
Cumulative	68/176	39

*Test of cure visits not included. Each subject counted only at the time of first recurrence, if she had more than one.

after completion of therapy.[4] Furthermore, a high proportion of persons with chlamydial infections who come to a sexually transmitted diseases clinic have recurrent infections.[9] In a study performed in Indianapolis between Sept. 1, 1983, and April 15, 1986, 5722 persons attending a sexually transmitted diseases clinic were identified by culture as having a chlamydial infection. Of these, 2224 (39%) returned at least once during the same period because of symptoms or concern about having a sexually transmitted disease, and 573 (26%) were again infected with *C. trachomatis*—some on as many as five separate occasions.[9]

These observations led to a closer evaluation of recurrent chlamydial infection, particularly in the setting of concurrent gonococcal infection at the time of recurrence. It was observed that a high proportion of persons (47%) with concurrent gonococcal infection were again infected with the same serovar of *C. trachomatis.*[3] In patients with no gonococcal infection, recurrence of the same serovar was considerably less frequent (22%). This association between gonococcal infection and the same serovar recurrence persisted for more than a year. By contrast, in persons without gonococcal infection, same serovar recurrence was infrequent beyond 6 months.[9]

The most likely explanation of these findings is that a number of patients had not been cured of the original chlamydia infection, which was somehow reactivated by the gonococcal infection. In patients without gonorrhea, the occurrence of same serovar reinfections at less than 6 months may represent either relapses or reinfections from untreated partners. In this group, however, most reinfections after more than 6 months involve a different serovar and presumably represent a new exogenous infection. If the original serovar was still present at the time of the second infection, it would have been replaced by the newly infecting serovar, perhaps by further stimulation of the immune response.

Preliminary data from another study in adolescent girls also indicate a high rate of recurrence.[10] Adolescent girls attending county health department clinics, primarily for contraception, pregnancy testing, and other gynecologic services, were cultured for *C. trachomatis* and followed up, respectively. One hundred seventy-six girls with positive cultures had a negative culture result within 3 months after treatment and had a second culture taken at a subsequent return visit, which was usually for contraceptive purposes (Table I). At each evaluation after the first 3 months, a recurrence rate greater than 20% was observed, with a cumulative rate of 39% for the entire 2-year follow-up period.

Distinguishing relapse from same serovar reinfection is particularly difficult in this population. None of the women was abstinent during the interval between infections, and many resumed sexual activity with a former partner who had not been treated for a chlamydial infection. Nevertheless, these data suggest that little if any protection against reinfection results from a natural infection and that persistence may represent more of a problem than is generally recognized.

Other evidence supporting such a concept includes the documentation of persistent *C. trachomatis* infection in infants for as long as 2 years,[11] as well as persistent infection with lymphogranuloma venereum strains for as long as 20 years in persons not likely to have been reinfected.[12]

In addition, there is an animal model in which persistence of sexually transmitted chlamydia infection is observed. Guinea pigs infected intraurethrally with low doses of the guinea pig inclusion conjunctivitis agent may have no evidence of infection and become culture negative. Yet they remain capable of transmitting the agent to other guinea pigs.[13]

Infertility and antibiotic resistance

Persistent infection may also be a contributing factor to infertility in women. We recently reported the recovery of *C. trachomatis* from the fallopian tubes and endometrium of 8 of 52 women (15%) undergoing microtuboplasty for tubal infertility.[14] In two women who had received tetracycline before microtuboplasty, the organisms were relatively resistant to tetracycline in vitro.[15] These isolates were also resistant to erythromycin, clindamycin, and sulfamethoxazole but were sensitive to ciprofloxacin, ofloxacin, and rifampin. One of the patients was treated with minocycline after microtuboplasty. She had a culture negative result in the lower genital tract and conceived. The other patient was lost to follow-up.

Table II. Eradication of *C. trachomatis* by β-lactam antibiotics and erythromycin

		Bacteriologic cure rate		
Site infected, reference	*Antibiotic*	*Day 7**	*Day 14*	*%*
Urethra (F)/cervix	Pivampicillin, 700 mg 2 times a day for 7 days	26/26	26/26	19
	Erythromycin, 500 mg 2 times a day for 7 days	23/23	22/23	
Urethra (M)	Amoxicillin, 750 mg 3 times a day for 7 days		11/11	20
Cervix	Ampicillin, 3.5 gm loading dose, then 500 mg 4 times a day for 7 days		10/12	21
Cervix (postpartum)	Timentin (5), piperacillin (2)		6/7†	22
Cervix (postpartum)	Cefoxitin (2), cefotetan (1)		0/3	
Endometrium (Salpingitis)	Cephalosporin		2/10‡	23

*After initiation of therapy.
†Three to 58 days after completion of therapy.
‡Type of follow-up cultures not specified.

The clinical significance of the type of resistance observed in these isolates remains to be determined. It was heterotypic, because only a small proportion of organisms in each isolate showed high-level resistance to tetracycline after in vitro growth.[15] Consequently, both a high inoculum and immunofluorescent staining of inclusions were necessary to demonstrate resistance. In addition, the resistant isolates did not grow well in vitro and may have had limited in vivo viability.

Erythromycin and β-lactam antibiotics

Treatment of chlamydial infections in pregnancy has proved to be a particularly difficult problem. Tetracycline cannot be used, and many pregnant women cannot tolerate the gastrointestinal side effects associated with erythromycin.

However, in one study in which oral erythromycin ethylsuccinate was given to infected pregnant women at a dose of 400 mg four times a day, cure rates of 92% were observed. Only 3% of subjects discontinued medication because of gastrointestinal intolerance.[16]

In a subsequent study in pregnant women, oral amoxicillin, 500 mg three times a day for 7 days, was compared with an oral erythromycin base, four times a day for 7 days. There was a slightly higher cure rate in the amoxicillin-treated women, and the regimen was better tolerated.[17] In a much smaller study nine infected, pregnant women were treated with comparable doses of amoxicillin for 10 days, and three were not cured.[18] Thus although further evaluation is in order, amoxicillin appears to be an acceptable alternative to erythromycin when erythromycin cannot be tolerated.

Limited data indicate that when given for several days, penicillins or erythromycin may also be effective for the treatment of chlamydial infections in other situations (Table II).[19-23] However, to date, single-dose or short-course therapy has been ineffective,[20] and cephalosporins have not been effective treatment when tried in patients.[23]

Table III. In vitro activity of selected antimicrobial agents against *C. trachomatis*

Antimicrobial agent	*MIC range (μg/ml)*
Tetracycline	0.02-0.5
Doxycycline	0.03-0.05
Erythromycin	0.05-0.5
Clindamycin	0.25-2.0
Azithromycin	0.26-1.02
Ampicillin	0.2-50
Sulfamethoxazole	4-50
Rifampin	0.005-0.25
Ofloxacin	0.5-2.0
Ciprofloxacin	1.0-4.0
Fleroxacin	1.5-2.5
Lomefloxacin	2.0-4.0
Perfloxacin	2.0-8.0
Norfloxacin	8.0-16.0
Enoxacin	8.0-16.0

New antimicrobials

Some of the fluoroquinolones and the azalide antibiotic, azithromycin, demonstrate significant promise for the treatment of chlamydial infections. Table III outlines the in vitro susceptibility of *C. trachomatis* to several of these agents.[24-28]

Ciprofloxacin was one of the first fluoroquinolones to undergo clinical trials for the treatment of chlamydial infections.[29, 30] Despite excellent in vitro activity, a substantial incidence of late failures was observed when patients had cultures taken 2 or more weeks after completion of therapy. Norfloxacin is ineffective in the treatment of chlamydial infections.[25] Ofloxacin demonstrated in vitro activity comparable with that of ciprofloxacin; however, therapy with a 7-day course of this drug resulted in a 99% cure rate, which is comparable with that of a full course of doxycycline.[31]

Because of the prolonged chlamydial life cycle of 48 to 72 hours, effective antibiotic treatment requires therapeutic levels of a drug at the intracellular site of infection for sustained periods of time. Standard treatment regimens entail multiple daily doses of antibiotic for at least 7 days. Compliance is often poor and recurrence remains a problem. Achieving medical compliance in the sexual partner of the index patient is an additional challenge to eradicating the chlamydial infection.

Azithromycin concentrates extensively within cells and has a tissue half-life of approximately 60 hours.[32] Azithromycin levels in human tissues after a single 500 mg dose may exceed the minimum inhibitory concentration of *C. trachomatis* by threefold to 10-fold for as long as 5 days. Clinical trials are examining the efficacy of twice that dose, 1 gm, for the treatment of chlamydial urethritis and cervicitis. If effective, a single-dose regimen with azithromycin would ensure adequate therapy and eliminate the compliance problem.

In two published studies, one conducted in Iceland[33] and the other in Finland,[34] a single 1 gm dose of oral azithromycin was as effective as 100 mg of doxycycline given twice a day for 7 days in eradicating urogenital *C. trachomatis* infections in both men and women. Side effects, primarily gastrointestinal, were mild and of similar incidence in the doxycycline and azithromycin groups. Additional data from two multicenter European studies seem to confirm these observations.[35]

In summary, new approaches to the treatment of chlamydial cervicitis and urethritis include compounds from the azalide and fluoroquinolone classes. Azithromycin, the first of the azalide antibiotics, offers the promise of efficacious single-dose therapy, an advance that should significantly improve control of this pathogen and help in the prevention of its serious sequelae.

Summary

Standard tetracycline, doxycycline, or erythromycin therapy appears to be effective against *C. trachomatis* infection under most circumstances. Doxycycline has been the preferred treatment because less frequent administration is required.

Nevertheless, test-of-cure cultures obtained 4 to 7 days after completion of standard therapy indicate a failure rate of approximately 5%. Frequent recurrence of the same chlamydial serovar in patients with gonococcal infections also suggests that the original infection may not have been cured.

A new azalide antibiotic, azithromycin, has been undergoing intensive clinical investigation as single-dose therapy for chlamydial urethritis and cervicitis. A single 1 gm dose has shown efficacy comparable with a standard 7-day course of doxycycline. The side effect profile has been mild, with an incidence similar to that of doxycycline. Effective single-dose therapy of chlamydial infections with azithromycin will significantly reduce compliance problems and enable greater control of chlamydia in the general population. It is hoped that this will ultimately reduce the serious sequelae caused by the pathogen.

The role of azalide antibiotics in the treatment of chlamydia

Raymond B. Johnson, MD
Groton, Connecticut

Chlamydia trachomatis causes an estimated 4 million infections each year in the United States. Sequelae in women include infertility and ectopic pregnancy. Doxycycline, the current standard therapy, must be taken twice daily for at least 7 days. Patient compliance is often poor, leading to recurrent disease. Azithromycin, a new antibiotic of the azalide class, achieves high and sustained intracellular levels and demonstrates excellent in vitro activity against *C. trachomatis*. Reported herein are the results of three comparative clinical trials, which demonstrate that single-dose oral therapy with azithromycin is as effective as a standard 7-day twice-daily course of doxycycline in the treatment of uncomplicated genital infections caused by *C. trachomatis*. (AM J OBSTET GYNECOL 1991;164:1794-6.)

Key words: Chlamydia, gonorrhea, doxycycline, azithromycin

Chlamydial infection is the most frequently encountered sexually transmitted disease in developed countries today, with an estimated 4 million infections each year in the United States alone.[1, 2] *Chlamydia trachomatis* is a bacterium that infects humans as an obligate intracellular parasite. Its life cycle is prolonged and is characterized by serial transformation between infectious and replicative forms. The genital serovars of *C. trachomatis* can cause devastating medical complications. Chlamydial infection of the cervix may ascend within the female genital tract and result in endometritis or salpingitis. This, in turn, may lead to tubal scarring, with resultant ectopic pregnancy or infertility. A newborn infant exposed to chlamydia in the birth canal may develop conjunctivitis or pneumonitis.[1] In men, *C. trachomatis* is a cause of urethritis, epididymitis, and proctitis.

Whereas urethritis and cervicitis caused by *Neisseria gonorrhoeae* are readily treated with single-dose regimens, standard therapy for *C. trachomatis* is problematic. The Centers for Disease Control currently recommends oral treatment of uncomplicated urethral, endocervical, and rectal infections caused by *C. trachomatis* with either doxycycline, 100 mg twice daily for 7 days, or tetracycline, 500 mg four times daily, for the same period of time. The inconvenience of multiple-dose therapy with doxycycline or tetracycline may lead the patient to discontinue therapy prematurely, with the possibility of resultant treatment failure. Because of this problem, there is a strong need for a single-dose therapy of *C. trachomatis* that is safe, effective, and well tolerated.[3-5]

Azithromycin: Spectrum and pharmacokinetics

Azithromycin is the prototype azalide antibiotic chemically related to erythromycin. It differs from that agent by virtue of its microbiologic spectrum, tolerability, and completely novel pharmacokinetics. Important sexually transmitted pathogens in the spectrum of azithromycin include *C. trachomatis*, *N. gonorrhoeae*, *Treponema pallidum*, and *Haemophilus ducreyi*, the causative agent of chancroid.

The pharmacokinetics of azithromycin are unique. It is avidly taken up by cells, resulting in high and sustained concentrations in tissues. A natural drug delivery system occurs as migratory leukocytes loaded with azithromycin are carried to sites of inflammation, further increasing local drug concentration.[6]

Azithromycin is acid stable, and bioavailability after a single 500 mg oral dose is 37%. The peak serum level after this dose is only 0.4 μg/ml; however, concentrations within tissues and cells are from 10- to 50-fold higher than in serum (Fig. 1). After oral administration, serum concentrations of azithromycin decline in a polyphasic pattern, resulting in an average terminal half-life of 68 hours. The high values for apparent steady-state volume of distribution (31.1 L/kg) and plasma clearance (630 ml/min) suggest that the prolonged half-life is from extensive uptake and subsequent release of drug from tissues. Excellent drug levels are attained in the ovary, fallopian tubes, uterus, and cervix (Table I).[7] Tissue levels of azithromycin are well in excess of the minimal inhibitory concentrations of most commonly encountered pathogens, and tentative guidelines suggest that susceptible organisms be considered those with minimal inhibitory concentrations of 90% that are less than or equal to 2.0 μg/ml.[8]

Clinical experience with azithromycin

The high and prolonged tissue concentrations of azithromycin allow its administration on a once-daily basis, with a shorter course of therapy (1 to 5 days) than

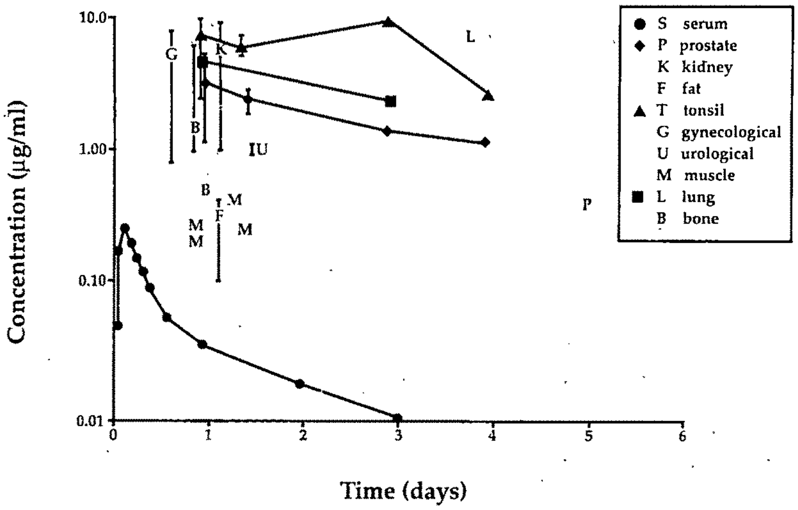

Fig. 1. Human serum and tissue concentrations after administration of 500 mg of azithromycin.

with standard agents. These unique pharmacokinetics, in conjunction with the excellent in vitro efficacy against *C. trachomatis*, suggested exploration of the efficacy of short-course oral therapy with azithromycin in the treatment of uncomplicated genital infections caused by chlamydia. The results of three trials performed in Europe, which involved more than 500 patients, are presented. All studies compared azithromycin therapy, administered as one to three doses, with 7-day twice-daily therapy with doxycycline. Tests for *C. trachomatis* were performed by culture in McCoy cells on swab specimens obtained from the urethra or endocervix. Positive cultures were identified when monoclonal antibodies bound successfully to chlamydial inclusions.

Single-dose efficacy. The first study* was designed to assess the safety and antichlamydial efficacy of a single 1 gm dose of azithromycin compared with a standard regimen of doxycycline, 100 mg twice daily for 7 days. One hundred forty-eight patients from 12 centers were treated with azithromycin, and 143 were treated with doxycycline. Eradication of *C. trachomatis* in evaluable patients was assessed 1 and 2 weeks after the initiation of therapy. At 1 week, 61 of 66 patients (92%) treated with azithromycin had eradication of the pathogen compared with 36 of 39 patients (92%) treated with doxycycline. At 2 weeks, the eradication rates for azithromycin and doxycycline were 96% (49/51) and 95% (36/38), respectively. Side effects were of mild to moderate severity, mostly related to the gastrointestinal tract, and were comparable for both agents (Table II). This study provided the first evidence that a single-dose regimen of azithromycin was comparable with a 7-day (14-dose) regimen of doxycycline in the treatment of uncomplicated genital chlamydial infections.

Table I. Azithromycin concentrations in human tissues 17 hours after oral administration of 500 mg

Tissue type	*No. of gynecologic tissues*	*Mean tissue concentration (µg/gm)*
Fallopian tube	5	3.3
Ovary	5	2.7
Uterus	4	3.5
Cervix	3	2.8
Fibroid tissue	1	2.2
Peritoneal adhesion	1	4.0
Serum	7	0.036
Peritoneal fluid	7	0.078

Table II. Results of study 1: Single-dose azithromycin*

	Azithromycin		*Doxycycline*	
Time period	*Total response (%)*	*Female response (%)*	*Total response (%)*	*Female response (%)*
Wk 1	61/66 (92)	28/29 (97)	36/39 (92)	23/24 (96)
Wk 2	49/51 (96)	22/23 (96)	36/38 (95)	22/23 (96)

*Treatment-related side effects: azithromycin, 35 of 148 (24%); doxycycline, 29 of 146 (20%). Most were of mild to moderate severity of the gastrointestinal tract.

A second study† examined the safety and efficacy

---

*Investigators in study 1 included the following: Professor P. M. Carsten, Germany; Dr. M. Dubois, Belgium; Dr. J. B. Garrel, France; Dr. A. Hallen, Sweden; Dr. E. Kutzer, Germany; Dr. J. G. Lauritsen, Denmark; Dr. K. Lind, Sweden; Professor P. Morel, France; Dr. P. Normand, France; Dr. R. Oitnner, Germany; Dr. F. H. F. Plantema, The Netherlands; and Dr. F. Verbeeck, Belgium.

†Investigators in study 2 included the following: Drs. E. T. Houang and A. G. Lawrence, United Kingdom; Dr. K. Krohn, Sweden; Professor A. Lassus, Finland; Dr. R. N. T. Thin, United Kingdom; Dr. S. Ullman, Denmark; and Dr. K. Weisman, Denmark.

Table III. Results of study 2: Two regimens of azithromycin*

	Azithromycin		*Doxycycline*	
Time period	*Single dose*	*3 Days*	*200 mg day/100 mg × 6 days*	*200 mg/day*
Wk 1	34/34	43/43	2/2	36/38 (95%)
Wk 2	34/35 (97%)	30/31 (97%)	6/6	27/28 (96%)

*Treatment-related side effects: azithromycin, 15/196 (8%); doxycycline, 6/96 (6%). All were of mild to moderate severity of the gastrointestinal tract, and no treatment was discontinued because of side effects.

Table IV. Results of 4-week follow-up study*

	Azithromycin			*Doxycycline*
Time period	*Single dose*	*1 Day*	*3 Days*	*200 mg/day × 7 days*
Wk 1	72/73	20/20	20/20	63/64 (98%)
Wk 2	68/70 (97%)	22/22	20/20	59/59
Wk 4	62/64 (97%)	17/18 (94%)	19/19	58/58

*Treatment-related side effects: azithromycin, 18/164 (11%); doxycycline, 11/83 (13%). Most were of mild to moderate severity of the gastrointestinal tract, and no treatment was discontinued because of side effects.

1 gm of azithromycin, administered either as a single dose or in divided doses over 3 days (500 mg on day 1, followed by 250 mg on 2 successive days). Control groups were treated with doxycycline, 100 mg twice daily for 7 days, or 200 mg on day 1, followed by 100 mg daily for 6 additional days. Data on the eradication of chlamydia at the 1- and 2-week assessments are presented in Table III. As can be seen, eradication rates in all groups were comparable at the 2-week follow-up visit. In addition, the safety profiles were also comparable.

Eradication of chlamydia: Four-week follow-up. An additional study was performed by Dr. O. Steingrimsson from Iceland to assess eradication of *C. trachomatis* at 1, 2, and 4 weeks after therapy with azithromycin or doxycycline. Azithromycin was administered in three different regimens for either 1 or 3 days (1 gm orally for 1 dose; 500 mg orally every 12 hours on 1 day; or 500 mg orally on day 1, followed by 250 mg daily for the next 2 days). Control patients were treated with oral doxycycline 100 mg twice-daily for 7 days. All regimens showed comparable efficacy (Table IV). Effective eradication was confirmed by 1-, 2-, and 4-week follow-up cultures. Again, the safety profiles were comparable.

Clinical trials have shown that a single 1 gm dose of azithromycin is safe and effective in the treatment of uncomplicated genital infections caused by *C. trachomatis*. Results compared favorably with multiple-dose therapy with doxycycline, the current "standard therapy." Patient compliance with multiple-dose regimens is a major concern in the treatment of sexually transmitted diseases.[9] The convenience and efficacy of single-dose therapy with azithromycin are expected to provide significant benefit in the clinic, because compliance with therapy is virtually assured.
